Preface to Developmental Psychopathology, Second Edition

It has been over a decade since the first two volumes of *Developmental Psychopathology* were published. These volumes were extremely well received: They have been highly cited in the literature and they have served as a valuable resource for researchers and practitioners alike. The expansion of the second edition of *Developmental Psychopathology* from two to three volumes speaks to the continued growth of the field, as well as to the ascendance of theory and research in the area of neuroscience informed by a developmental perspective.

There can be no doubt that the discipline of developmental psychopathology has grown significantly in a relatively short period of time. The more than 30 years that have elapsed since the initiation of the Schizophrenia high-risk projects (Garmezy & Streitan, 1974) have been marked by significant contributions to the field. Noteworthy among these are the publication of Achenbach's (1974) first text, Rutter and Garmezy's (1983) chapter in the *Handbook of Child Psychology*, and the continued growth of the journal *Development and Psychopathology*, including the Millennium Special Issue entitled *Reflecting on the Past and Planning for the Future of Developmental Psychopathology* (Cicchetti & Sroufe, 2000). A not insignificant contributor to this rapid growth can be found in the very definitional parameters of the discipline. Theorists and researchers in the field of developmental psychopathology use a lifespan framework to elucidate the many factors that can contribute to the development of mental disorders in individuals at high risk, as well as those operative in individuals who have already manifested psychological disturbances or who have averted such disorders despite their high risk status. In essence, a developmental psychopathology perspective provides a broad, integrative framework within which the contributions of diverse disciplines can be incorporated and enhanced (Cicchetti & Sroufe, 2000). Thus, rather than having to develop new theories and methods, those

working within a developmental psychopathology framework can build on and extend previously established traditions. The ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary research will expedite growth within the field of developmental psychopathology.

As with the previous edition, the current volumes were not organized exclusively around thematic psychiatric disorders. Rather, authors were encouraged to explore developmentally relevant theories, methods of assessment, and domains of functioning. Although many chapters do address specific psychiatric disorders, it is the processes that contribute to the emergence of psychopathology that are emphasized rather than the psychiatric disorders per se.

Volume I, *Theory and Method*, presents various approaches to understanding developmental influences on risk and maladaptation. As previously, the volume begins with an explication of the discipline of developmental psychopathology. Within this chapter, a number of significant advances within the field are noted, including the increased attention to processes and mechanisms, the use of multiple levels of analysis, the rise of developmental neuroscience, and the evolution of translational research paradigms. Chapters address a range of topics, including approaches to diagnoses of disorders, developmental epidemiology, diverse theoretical perspectives, various contextual issues, and new frontiers in statistical techniques for developmental phenomena. The volume concludes with a chapter on prevention and intervention.

Volume II, *Developmental Neuroscience*, was added to acknowledge the significant growth in this area since the publication of the first edition of this *Handbook*. Given the seminal historical role that neuroscience played in the emergence of developmental psychopathology (Cicchetti, 1990; Cicchetti & Posner, 2005), it is only fitting that developmental neuroscience has both informed and been informed by developmental psychopathology theorizing.

Neural plasticity, brain imaging, behavioral and molecular genetics, stress and neurobiology, immunology, and environmental influences on brain development are covered in this volume.

Volume III, *Risk, Disorder, and Adaptation* presents various perspectives on contributors to disorder. For example, chapters address the role of social support, family processes, and early experience on adaptation and maladaptation. Other chapters address specific disorders, including mental retardation, language disorders, Autism, disorders of attention, obsessive-compulsive disorders, Tourette's syndrome, social anxiety, Schizophrenia, anti-social disorders, substance abuse, and dissociative disorders. A number of chapters on resilience despite adversity also are included. The volume concludes with a chapter on stigma and mental illness.

All authors were asked to conclude their chapters with discussions of future research directions and needs. Thus, these volumes serve not only to highlight current knowledge in the field of developmental psychopathology, but also to suggest avenues to pursue for progress to continue. In particular, it is increasingly important to incorporate multiple-levels-of-analysis approaches when investigating maladaptation, psychopathology, and resilience (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). The examination of multiple systems, domains, and ecological levels in the same individuals over developmental time will yield a more complete depiction of individual patterns of adaptation and maladaptation. Moreover, such methods are likely to be extremely valuable in elucidating how interventions may affect brain-behavior relations (see, e.g., Caspi et al., 2002, 2003; Cicchetti & Posner, 2005; Fishbein, 2000; Goldapple et al., 2004; Kandel, 1979, 1998, 1999). Such endeavors could result in significant progress toward understanding psychopathology, highlighting efficacious interventions, and ultimately decreasing the burden of mental illness (Cicchetti & Toth, in press).

I now turn to more personal considerations. Although Donald Cohen is no longer with us, he worked closely with me as we developed our plans for the second edition of *Developmental Psychopathology*. Given our collaboration on the first edition of the volumes and our discussions leading up to the publication of these volumes, I thought it only fitting that he be listed as my coauthor. I believe in my heart that Donald would be pleased to have his name affiliated with these volumes and when I shared this plan with his wife, Phyllis, she gave her enthusiastic endorsement. However, I hasten to add that, unfortunately, Donald's illness and untimely death precluded his active involvement in editing the chapters in these volumes. Thus, despite our many

conversations as the plan for these volumes unfolded, I alone am responsible for the final editing of all chapters.

In closing, I want to dedicate these volumes to my dear friend, Marianne Gerschel. Marianne is a true visionary and she has contributed significantly to my work in the area of developmental psychopathology. Without her belief in the value of this field, my efforts and accomplishments would have been greatly compromised.

Finally, as I write this preface, I am ending a significant era in my life. After more than two decades as the director of Mt. Hope Family Center, I am leaving Rochester to accept a position at the Institute of Child Development, University of Minnesota. There I will be the director of an interdisciplinary center that will emphasize a multiple-levels-of-analysis approach to research and intervention in developmental psychopathology.

This transition is difficult, as Mt. Hope Family Center and my colleagues there have contributed greatly to the growth and development of the field of developmental psychopathology. It is reassuring to know that Mt. Hope Family Center will continue to build upon a solid foundation under the capable directorship of my long-time collaborator and friend, Sheree L. Toth. Although I welcome the new opportunities and challenges that await me, I cannot help being a bit sad to leave. My spirits are buoyed by the knowledge that my work at Mt. Hope Family Center will continue and by my excitement at returning to my roots at the Institute of Child Development where I will have both University and community support to use the field of developmental psychopathology to extend my vision for helping disenfranchised individuals and families throughout the nation and the world.

REFERENCES 31

People commonly rely on the support of others in everyday circumstances. Friends and family offer emotional encouragement in times of stress. Coworkers and neighbors provide information and material assistance as it is needed. We turn to trusted friends and colleagues for helpful advice. Marital and romantic partners monitor the well-being of those they care for. Social support is among the most important features of the relationships that support healthy psychological functioning.

At times, social support is also offered in formal helping relationships. Physicians, religious advisors, social workers, and other professionals provide social support as part of their role responsibilities. Social support is a critical function of many approaches to psychological therapy, of course, whether the support is received from an individual mental health professional, a therapy group, or a special preschool, classroom, or adult education program designed to assist troubled individuals. In many respects, the efforts of formal helpers are meant to emulate the kinds of social support obtained from the most helpful individuals in natural support networks.

The relevance of social support to developmental psychopathology derives from its relationship to the etiology, maintenance, and treatment of childhood psychologi-

cal disorders. First, inadequate social support, often in the context of social isolation or dysfunctional social relationships, can contribute to the development of psychological problems in children. Children who face social adversity without the buffering assistance of supportive relationships are at a higher risk of developing clinical problems, especially if they encounter adversity in the home. This is why many preventive interventions for at-risk children and families emphasize strengthening formal and informal forms of social support, such as through home visitation programs. Second, for children with psychological disturbances, social support may help to diminish their problems, and lack of support can exacerbate their difficulties. Social support can assist in coping, increase children's social skills, and help them and their families access needed services. Conversely, many clinical conditions in childhood, including depression, conduct disorders, and child maltreatment, cause children to alienate or resist social support and to become further isolated within their families, peer groups, and communities. Enhancing existing avenues of social support and creating new ones thus becomes central to effective intervention. For this reason, most approaches to therapy for children enlist social support, whether in the context of group therapy, peer mentoring, parent education

2 Social Support and Developmental Psychopathology

or parent support groups, social skills training, therapeutic preschool programs, mother-child psychotherapeutic intervention, or other avenues. Understanding the nature of social support and its relevance to psychological well-being and restoration improves understanding of the development and treatment of child clinical disorders.

Because social support is so often a part of everyday experience, it is easy to expect that social support can be straightforwardly provided to troubled children and families, and that there will be direct benefits from doing so. It is surprising, therefore, when socially isolated families actively resist efforts from supportive social networks, or home visitors quickly become exhausted by their efforts to provide assistance to at-risk families, or children in emotional turmoil continue to alienate those attempting to assist them. The same conditions that contribute to social isolation, in other words, make the enlistment of social support especially difficult. Social support is thus easy to conceptualize but difficult to implement in the lives of troubled children and their families. This has been the hard lesson of recent years of efforts to enlist social support into preventive and therapeutic efforts on behalf of children at risk. As a result, although clinicians and researchers remain convinced that social support is beneficial, they have become more aware that formal efforts to provide social support can be frustrated even when they are designed to emulate or build on the natural sources of support on which people commonly rely. Further, enlisting natural sources of support for therapeutic purposes can be challenging and, at times, problematic. Researchers and practitioners are only at the beginning of understanding and overcoming the obstacles that exist to providing social support as a component of preventive and treatment efforts.

Our goal is to profile the multifaceted ways that social support is relevant to developmental psychopathology. In the section that follows, we consider how to define social support and its functions in the lives of children and adults, drawing on the importance of social networks to developmental adaptation. Next we consider social support within the broader social context of development and psychopathology. This requires considering the independent and overlapping social networks of children and parents, developmental changes in support needs and capacities to elicit support, and the importance of peers and the community. We then examine social support in relation to psychopathology, discussing the role of support—or its absence—in the onset of clinical problems, their maintenance over time, and their remediation. Social support is relevant to etiological, maintenance, and treatment concerns in different and complex ways, in other words, and distinguishing among them emphasizes how social support and the absence of support has diverse applications to the problems of troubled children and

families. In the next section, we try to understand the influences that can enhance or frustrate the efficacy of social support efforts, whether they occur in natural social networks or in formal interventions. These include clarity (or lack of it) concerning the intended goals of support, the needs of providers of support, and the complex reactions to receiving assistance from another. We also consider the cultural and community context of social support. From these considerations, we then proceed to profile the implications of these contingencies for interventions that have the goal of providing or enhancing social support, and consider the lessons learned for future efforts. We integrate these ideas in a concluding section in which we consider future directions for research and intervention.

WHAT IS SOCIAL SUPPORT? WHY IS IT IMPORTANT?

Because social support is such a familiar feature of everyday life, it is easy to assume that it is readily understood and that most people experience social support in comparable ways. Yet, a thoughtful analysis of what social support is and does reveals that it is both more multidimensional and more complexly offered and received than we often assume. Consider, for example, the following definition: “Social support consists of social relationships that provide (or can potentially provide) material and interpersonal resources that are of value to the recipient, such as counseling, access to information and services, sharing of tasks and responsibilities, and skill acquisition” (Thompson, 1995, p. 43). Embedded in this definition are several features of social support that underscore its complexity.

First, social support is given and received in the context of relationships, and relationships are psychologically complex (Badr, Acitelli, Duck, & Carl, 2001). Support may be obtained from relationships within natural social networks—such as with parents or offspring, extended kin, coworkers, teachers, peers, neighbors—or formal helping relationships, such as with a religious advisor, mentor, physician, mental health professional, social worker, or other professional.¹ The nature of the relationship deter-

¹ To be sure, social support usually but does not always occur in the context of relationships. For example, crisis hotline (and “warm-line”) services can provide advice, support, and referrals for individuals who need immediate assistance, including children (see Peterson, 1990). For people who would otherwise resist the risks of discussing personal problems with a friend or counselor, the anonymous self-disclosure offered by services like these can be of benefit.

mines what kinds of support are possible and the limitations that may exist in receiving social support. On the broadest level, for example, some individuals are support generalists who provide many kinds of assistance, whereas others (especially people in formal helping relationships) are support specialists who have one particular form of social support to offer (Bogat, Caldwell, Rogosch, & Kriegler, 1985). The kind of assistance received from each person—and the circumstances in which one would seek their help—are likely to differ considerably.

The roles of relational partners also shape the support they can offer and limitations in that support. Extended family members, for example, can offer emotional guidance and understanding based on long-standing, close relationships. But the assistance of a relative may be colored by family traditions or a legacy of family conflict, and multi-generational assistance is often complicated by conflicting responsibilities to different generational networks (e.g., one's obligations to adult siblings may conflict with providing assistance to their offspring, especially when the latter are troubled by family problems). Neighbors can provide referrals to local help givers, material aid, emergency assistance, and respite child care. But in communities at risk, neighbors may experience the same economic and ecological problems as do the families who need their assistance, and neighbors may thus have little to offer because of their own needs. Neighbors may also be as concerned with distancing themselves from a family in turmoil as they are with providing aid. Peer friendships and group acceptance may buffer loneliness for a shy child and work in concert with other protective factors to prevent depression. But if the child's shyness leads to withdrawal that discourages age-mates from interacting with the child, the peer response may increase the child's vulnerability and enhance, rather than diminish, loneliness and vulnerability to depression.

The same "situation specificity" of relationships (Unger & Powell, 1980) is also true of formal support agents. A social worker may offer valuable assistance by connecting families to community resources and providing informal counseling. But an overwhelming caseload may diminish the caseworker's reliability or limit the other kinds of assistance that can be provided. A doctor or minister may be a source of professional guidance and can offer an expert and dispassionate perspective on family problems, but professional training and role definitions may shape the kind of support that is offered. Problems may be viewed through the prism of a professional's specialized expertise or background, for example, such that the kind of assistance that is offered (e.g., medication, counseling, referral) may or may not be what is really needed by the recipient. In other circumstances, the role responsibilities of professional helpers

may curb the involvement of other potential helpers. It is well-known, for example, that professionals who are legally mandated reporters of suspected child maltreatment are typically aware of many more child abuse cases than they formally report. This owes, in part, to the complications introduced into their professional relationships with families once a child abuse investigation has been inaugurated and the preference of many helping professionals to address family problems on their own (Zellman, 1990; Zellman & Anter, 1990). But their failure to enlist legal authorities means that additional sources of support are unavailable to families who might need them, and the clinician assumes a heavy burden of responsibility. Social support is thus mediated by the relationships through which it is offered and the other roles and responsibilities of those relationships.

Other features of relationships are also important to offering and receiving social support. In natural social networks, for example, assistance is usually provided in two-way relationships of mutual aid, where individuals can be providers as well as recipients of help. This helps to ensure feelings of mutual respect that contribute to relational satisfaction. When help giving is unidirectional, or when it occurs at considerable cost to the helper, it can make the recipient feel indebted and, as a consequence, inferior and vulnerable, and this can quickly undermine a helping relationship (Fisher, Nadler, & Witcher-Alagna, 1982; Shumaker & Brownell, 1984). When children are the recipients of social support from adults, the mutual obligations of help giving are less compelling because children are commonly recipients of one-way assistance. Nevertheless, their parents may feel indebted and vulnerable, especially if help giving is perceived as deriving from parental inadequacy. When children receive help from peers, mutuality may be especially important to the maintenance of the relationship and its positive influence. In formal helping relationships (such as with a counselor, therapist, or social worker), unidirectional assistance is part of the relationship and feelings of vulnerability are less likely. But formal relationships may be limited in the extent to which they influence the facets of a child's (or family's) private life in which assistance is truly needed. Thus, one of the significant challenges of offering social support in the context of relationships is understanding how support can be offered without the negative reactions that support can engender, especially when assistance is not bidirectional.

More generally, relationships are also complex constellations of mutual obligations that can offer support and affirmation but also create stress and difficulty, sometimes at the same time (Berscheid & Reis, 1998; W. A. Collins & Laursen, 1999). Belle's (1982) study of lower-income single mothers provocatively illustrates how their relationships

4 Social Support and Developmental Psychopathology

with extended kin, neighbors, and boyfriends afforded support but at the same time the risks of rejection, criticism, privacy violations, and entrapping demands that relationships with family and romantic partners often entail. Likewise, although peer relationships can offer considerable social support to children, association with deviant peers, especially in adolescence, has been associated with antisocial behavior (Dishion, Andrews, & Crosby, 1995; Laird, Jordan, Dodge, Pettit, & Bates, 2001). The relationships affording the greatest support often entail a complex calculus of assistance and demand in which risks accompany receipt of support. Thus, it is not always wise to assume that integrating needy individuals, or isolated families, into broader social networks will necessarily increase social support or ameliorate psychopathological processes. Deriving social support from social networks depends on characteristics of needy recipients and of others with whom they have relationships.

A second feature of this definition of social support is that it is multifaceted. It includes emotional encouragement but can also incorporate access to information and services, counseling and guidance, material assistance, sharing of tasks and responsibilities, and skill acquisition. The importance of each of these facets of social supports depends on what is needed and is of value to the recipient. For adults under stress, for example, one of the most important benefits of supportive relationships is the sense that one is not alone and that others are emotionally “on your side” with compassionate encouragement. For others, however, assistance is best provided when people are also brokers of information or services, such as when friends and neighbors are consulted for childrearing advice, referrals to child care providers or counselors, or access to community agencies where further information or resources can be obtained. For individuals in economic difficulty, material assistance (such as lending money or a car) and services (such as respite child care) is an important form of social support. For others, help in acquiring vocational or personal skills (such as financial management skills) is especially valuable. For many people in difficulty, social support is received as counseling, advice, and guidance about troublesome issues, whether related to marital difficulty, parenting problems, or managing emotional stress. Even in children’s peer relationships, social support is multifaceted. Parker and Asher (1993) found that the friendships of children who were highly accepted among their peers provided greater validation and caring, more help and guidance, greater conflict resolution, and more intimate exchange than friendships of children with lower peer acceptance. The friendships of children who were not well accepted were characterized by higher levels of conflict

and betrayal compared to the friendships of highly accepted children.

Of course, supportive relationships do not necessarily incorporate each of these facets of support, and, indeed, these features of support are not always complementary within relationships. Individuals who provide emotional encouragement to friends or neighbors may find it difficult, for example, to offer critical advice and still be perceived as supportive. This is the difficulty faced by those who urge family members or friends to reduce their smoking, drinking, or substance abuse as a way of improving family life or personal well-being. Their efforts to create more healthy practices in another may be perceived by the recipient as meddlesome and intrusive. In other circumstances, material assistance is deeply appreciated when it is freely offered, but if it becomes conditional on the recipient’s compliance with behavioral expectations (which can occur in families, religious groups, and adolescent peer groups), it loses its emotionally supportive qualities. A young adult may appreciate the financial assistance that derives from moving back to the parent’s home, for example, but the more limited freedom and parental monitoring that this entails may be experienced as demeaning and unsupportive.

When social support is viewed in the context of developmental psychopathology, there are additional potential facets of socially supportive relationships. Social support can be enlisted to monitor the well-being of at-risk children, such as when extended kin or a social worker regularly check in on a family member who is suspected of child neglect. In these instances, social support is enlisted for preventing harm. Social support can also be offered to improve parental conduct, such as through the guidance of a home visitor or the advice of a grandparent. By contrast with other forms of skill acquisition, its purpose is not only to enhance parental competency but also to indirectly benefit children by creating more positive, constructive parent-child relationships. Finally, social support can be enlisted for purposes of developmental remediation. As we shall explore further, supportive relationships contribute to psychological healing in children, whether via therapeutic child care programs that provide young children with secure attachments to caregivers, social skills training or peer mentors that help children experience more successful peer relationships, or individual therapy that focuses on the impact of problems on significant relationships. In these cases, supportive relationships are oriented toward treating troubled children and strengthening developing capacities that have been undermined by such problems as depression, conduct disorders, or parental abuse.

Taken together, these multifaceted qualities of social support have diverse applications to developmental psychopathology. Consider, for example, the challenges of preventing child maltreatment (Thompson, 1995). Families prone to child abuse are typically multiproblem families in economic difficulty, living in poor neighborhoods, and socially isolated from others in the community (Daro, 1988; Polansky, Chalmers, Bittenwieser, & Williams, 1981; Straus, Gelles, & Steinmetz, 1980). Child protection strategies often begin with integrating social support into family life, which can occur through a program of professional home visitation, efforts to strengthen neighborhood connections, enrolling parents in parenting classes, or through other community services. The general goals of such efforts are to reduce parenting stress through emotional support, strengthen parenting skills by providing developmental guidance and models of effective parenting practices, and monitor children's well-being through regular home visits or agency consultations. More ambitious efforts to prevent child maltreatment through social support sometimes include crisis counseling, material aid to families in economic distress, and programs to strengthen job skills or household competencies. When social support is enlisted to reduce abuse recidivism, interventions are typically more intensive, enduring, and focused than when social support strategies are part of a broader effort to prevent abuse in at-risk populations. The most intensive treatment programs, for example, can involve daily visits by a specially trained therapeutic social worker who works to reconstitute healthy family relationships (Thompson, 1995).

Social support alone is unlikely to be an effective answer to the complex problems faced by families at risk for child abuse or neglect or children facing the challenges of clinical disorders. But social support is probably an essential component of any multifaceted effort to prevent psychological difficulties in at-risk families and children or to provide therapeutic assistance when family problems have resulted in a troubled or harmed child. The challenge is to craft well-designed interventions that improve the support afforded by natural helpers and enlist the assistance of formal helpers, based on a careful assessment of the needs of the child or family at risk (Thompson & Ontai, 2000). Accomplishing this requires a thoughtful appreciation of the nature of social support, as well as the social context of development and psychopathology.

THE SOCIAL CONTEXT OF DEVELOPMENT AND PSYCHOPATHOLOGY

Whether the focus is on children's typical or atypical psychological growth, developmental psychopathologists are

concerned with how early patterns of individual adaptation evolve into later adaptations as developmental transformations occur in thinking, behavior, and emotion (Cicchetti & Cohen, 1995; Dodge & Pettit, 2003; Sroufe & Rutter, 1984). Among the many influences on psychological growth, relationships are central to how children adapt to the opportunities and challenges of each period of life. Understanding the relevance of social support to developmental psychopathology thus requires appreciating the social context of development and psychopathology, as well as developmental changes in children's access to broadening networks of social support in their natural environments.

From the beginning of life, infants depend on the solicitude of others for protection, nurturance, and well-being. A well-functioning parent-child relationship provides a supportive context for development despite variations in external resources (such as the family's economic status) or internal characteristics (such as the child's temperament) because it can buffer the effects of disadvantage and provide significant psychological resources for healthy growth. Indeed, this relationship can be regarded as being socially supportive in all the facets just described (e.g., emotional encouragement, providing material and interpersonal resources, sharing activity, fostering skill acquisition), and this is why infants and young children rely so significantly on the assistance and nurturance of their caregivers. Early in infancy, for example, babies become quiet in anticipation of the mother's arrival when they are distressed (Lamb & Malkin, 1986), enlist the emotional information in the mother's face when encountering uncertain or perplexing situations (Baldwin & Moses, 1996), and turn to the caregiver for assistance when they are fearful or distressed.

Variations in the quality of parental nurturance or sensitivity are important in young children's reliance on the support of their caregivers. An extensive literature on the security of attachment documents how young children develop secure relationships with caregivers who respond sensitively and appropriately to their signals and, conversely, develop insecure attachments when caregivers are inconsistently responsive (for reviews, see Cassidy & Shaver, 1999; Thompson, 1998). These variations in attachment security may be regarded as significant early differences in perceived support from caregivers on whom an infant must rely for emotional and physical well-being. These variations in security are apparent not only when young children are distressed but also in nonstressful circumstances, such as in the quality of emotional sharing between a toddler and an adult during play or social interaction. Differences in the security of attachment are,

not surprisingly, developmentally significant. Attachment security is associated with many features of psychosocial growth, including the quality of children's relationships with other people, their capacities to interact sociably with unfamiliar adults, emotion understanding and emotion regulation, self-understanding, and even conscience development (see Thompson, 1999, for a review). These findings are consistent with the theoretical view that from the security of their relationships with caregivers, young children derive broader representations of relationships, themselves, and other people that guide their subsequent social encounters and their expectations for future relationships (Bretherton & Munholland, 1999; Thompson, 1998, 2000).

Moreover, the support entailed in a secure or insecure attachment foreshadows continuing support in later years as children encounter later developmental challenges. In one study, children's perceptions of emotional support from the mother at age 8 were predicted by the security of mother-child attachment at age 4 (Booth, Rubin, & Rose-Krasnor, 1998). Bost and her colleagues (1998) found that secure preschoolers had more extensive and supportive social networks and were also higher on sociometric assessments of peer competence (see Booth, Rubin, & Rose-Krasnor, 1998; DeMulder, Denham, Schmidt, & Mitchell, 2000, for similar results). Anan and Barnett (1999) also found, in a sample of lower-income African American 6½-year-olds, that secure attachment (assessed 2 years earlier) was associated with children's perceptions of greater social support, and social support mediated the association between secure attachment and lower scores on externalizing and internalizing problems. Viewed in the context of social support, therefore, young children derive foundational support from the parent-child relationship and are creating provisional representations from this relationship about the quality of support they can expect from others they encounter.

Responsive, warm parenting may thus be regarded as a protective factor in early psychological growth because of its positive psychological correlates and the confidence it inspires in parental responsiveness and because it creates more positive expectations of the support of others that may cause children to more competently elicit assistance when it is needed (Colman & Thompson, 2002). By contrast, parental harshness and unresponsiveness may be a risk factor for psychosocial problems, especially if parental behavior creates stress as well as being unsupportive. Consider, for example, the experience of young children living with a depressed parent (Cicchetti & Toth, 1998; Goodman & Gotlib, 1999; Zahn-Waxler & Kochanska, 1990). In these circumstances, children are emotionally attached to a mother who manifests a great deal of sad emotion, together

with irritability, helplessness, and blame of others, including offspring. In the context of this emotional climate, moreover, depressed caregivers act in ways that enhance children's sense of guilt and responsibility for the adult's depression. Depressed parents have high expectations for the behavior of offspring, and thus they can also be demanding and critical, using love withdrawal and other techniques to enforce compliance with their demands. It is easy to see how children living with a depressed parent are themselves at risk for psychological problems (Cummings & Davies, 1994, 1996). Their vulnerability to a parent's depression begins as early as infancy (Zeanah, Boris, & Larrieu, 1997). Young children are especially prone to becoming enmeshed in the parent's affective difficulties because their emotional attachments to these caregivers, even if they are insecure, makes their emotional well-being contingent on that of their parents.

Parents are primary sources of social support for children or, in the words of Cauce, Reid, Landesman, and Gonzales (1990), "support generalists." Parents also mediate children's access to other sources of social support, both formal and informal (Cochran & Brassard, 1979; Parke & Bhavnagri, 1989). Most generally, parents' choices of housing, neighborhoods, and schools affect the range of children's options for forming social connections with others outside the family, and frequent residential mobility limits the breadth of a child's social network (Ladd, Hart, Wadsworth, & Golter, 1988). Children growing up in troubled schools or dangerous neighborhoods simply have fewer options for creating and maintaining supportive social relationships with peers and adults than do children living in more constructive settings. Parents also commonly arrange, facilitate, and monitor their children's contact with others as gatekeepers of children's access to them. Parents schedule activities, provide transportation, and supervise offspring during social and recreational activities with friends and neighbors, especially when children are young (Ladd & Le Sieur, 1995). O'Donnell and Steuve (1983) reported that lower-income and middle-class mothers differed significantly in the access they provided their school-age children to community activities, with middle-class mothers participating extensively with their offspring in these programs (often as volunteers and aides) and lower-income mothers declining to commit themselves in these ways and instead permitting their children greater unscheduled freedom for "just being with friends." As children become capable of bicycling, using public transportation, and later driving independently to their activities, parents still retain an important monitoring role. They do so less directly, such as by granting permission to participate in activities, providing

funding, and consulting with offspring about their plans, but this supervision is developmentally appropriate by enlisting the adult's guidance in the increasingly independent social lives of their children. Parents also mediate children's contact with extended kin networks by facilitating opportunities to see grandparents and other extended family members or restricting access to them (Thompson, Scalora, Castrianno, & Limber, 1992).

In therapeutic contexts, of course, parents mediate children's access to clinical assistance not only by providing transportation but also by giving consent, paying for therapy, and supporting the clinician's efforts. When children are young, nearly all evidence-based treatments rely heavily on parental participation. Parental involvement is integral to therapies that decrease disruptive behavior problems, such as those experienced by children with Attention-Deficit/Hyperactivity Disorder (ADHD), Oppositional Defiant Disorder, or Conduct Disorder (e.g., Hembree-Kigin & McNeil, 1995; McMahon & Forehand, 2003; Webster-Stratton, 1998). Therapeutic interventions addressing internalizing disorders, such as anxiety (Kendall, Aschenbrand, & Hudson, 2003) or depression (Stark et al., 1996), require parental support to ensure that children complete therapeutic tasks in home, school, and neighborhood settings. This means that therapeutic assistance to children will be nearly impossible without the parent's cooperation (or tacit cooperation, in the case of adolescents). When children's difficulties arise from family problems or are maintained by family responses, parents may limit the effectiveness of treatment by denying that problems exist or resisting assistance. When parents experience their own mental health difficulties, obtaining therapeutic support for children can be challenging. This means that therapeutic efforts for children often require a two-generation approach in which the parent's needs receive attention as well as the child's, and this is especially true when social support is a central feature of the therapeutic effort.

The social networks of parents and offspring overlap in other ways. Parental networks have important consequences for children because they influence parents' well-being, offer opportunities to children for new experiences and relationships, and directly socialize parental behavior (Cochran, 1990; Cochran & Niego, 1995). Social support to parents has been found to improve parenting and, in doing so, to enhance many features of the psychological well-being of offspring, including attachment security, social competence, and emotional adjustment (see review by Thompson, 1995). Parents with many close friendships have offspring with better social skills and peer acceptance because, in part, of the peer relationships afforded by par-

ents' social contacts (Parke, 2002; Parke et al., 2002). However, parental social networks can be sources of stress as well as support, and children's well-being can be undermined by the difficulties that parents experience in their relationships with coworkers, neighbors, or extended kin. Relatives can be critical and demanding as well as supportive, and coworkers can offer helpful advice but also heighten workplace strain. Thus, the nature of parents' social networks can have helpful or unhelpful implications for family functioning and children's well-being.

The shared social networks of parents and offspring, and their potentially helpful and hurtful consequences for psychological well-being, are also illustrated by the associations of socioeconomic status (SES) with social support. For many reasons related to the impact of financial and job stress, neighborhood disorganization and danger, and lack of community resources, the social networks of families in poverty are likely to be less supportive and, at times, more stressful than those of families living in economically more advantaged conditions (e.g., Belle, 1982; Ceballo & McLoyd, 2002). Socioeconomic stress and community problems can have direct impacts on children. Lynch and Cicchetti (2002) noted, for example, that children who reported that they had been exposed to high levels of community violence also reported feeling less secure with their mothers.

The stresses associated with socioeconomic difficulty can also moderate the influence of social support on parenting, but relevant studies offer contrary portrayals of how this occurs. In a study of low-SES African American women, for example, Ceballo and McLoyd (2002) found that for women in more difficult circumstances (i.e., poorer and more dangerous neighborhoods), the positive associations between emotional support and nurturant parenting decreased, as did relations between instrumental support and diminished reliance on punishment. In short, the positive connection between social support and constructive parenting was strained and attenuated in poorer, more dangerous neighborhoods even though social support needs were greater. However, studying a large, nationally representative sample, Hashima and Amato (1994) reported that the negative association between maternal perceptions of social support and reports of punitive behavior were strongest in lower-income families. In other words, social support appeared to have the greatest benefits for mothers when socioeconomic stresses were greatest. Although more research is needed to clarify these differences in conclusions, each study confirms that the stress-buffering effects of social support may vary according to income and neighborhood quality. This is important because children and parents share the economic

conditions of the family, and thus the effects of income and neighborhood quality not only have direct effects on children (through the impact of neighborhood crime, poor schools, financial need, and related influences) but also indirect effects through the influence of stress and social support on parenting quality.

Research on the interaction of income with social support and stress is important also as a reminder that the social networks in which children and families live are not always potential sources of social support. At times, they are greater sources of stress and difficulty than of support. Indeed, one of the challenges of providing assistance to multiproblem families is that their living circumstances often do not provide avenues of informal social support because extended family members are in turmoil, neighbors and friends suffer from the same stress as do the targets of intervention, and communities are drained of potentially helpful social resources. This can make it difficult to find sources of support for needy families in difficult living conditions.

The intersection of parent and child social networks therefore has important implications for the association between developmental psychopathology and social support. When children's difficulties are associated with family problems, parents' social networks often do not provide meaningful support to the children. One of the characteristics of families at risk for child maltreatment is their social isolation, which significantly reduces potential sources of assistance for children (Limber & Hashima, 2002; Thompson, 1995). Within their more limited social networks, moreover, extended family and neighbors often fail to intervene when children are maltreated and may actually reinforce harsh parental attitudes and conduct that lead to abuse or neglect (Korbin, 1989, 1991). Thus, parents' social networks can exacerbate rather than help to remediate children's problems through their influences on parental conduct and family functioning. This is one reason child clinical problems must often be conceptualized as family problems when questions of etiology and treatment are concerned.

The overlap of social support networks for children and parents highlights the value of two-generation interventions for troubled children. Two-generation interventions are founded on the realization that treating a troubled child requires addressing the needs of the parent (and the family system) because a child's psychopathology and the remediation of clinical problems are typically associated with broader family difficulties and strengths. With respect to social support, two-generation interventions can include efforts to enlist the support of parents' social networks

when network members can provide assistance—and reduce the influence of network associates when they contribute to children's difficulties—as a means of enlisting supportive assistance for the child. Two-generation interventions are the basis for many preventive and therapeutic programs for at-risk children, such as home visitation programs that are discussed subsequently in this chapter. The importance of thinking multigenerationally emphasizes how problems in developmental psychopathology must be addressed in ways that are distinct from conventional adult therapeutic approaches because of the reliance of children on their parents and families and the overlap of their social support networks.

With increasing age, children depend less exclusively on their parents for their emotional well-being, yet parents' continuing importance as social support agents should not be underestimated. In adolescence, for example, striving for autonomy and independence is not inconsistent with continuing needs for parental support (Allen & Land, 1999). Even as peers become more important consultants on issues like appearance, style, and taste, parents remain preferred advisors on core moral values, political and religious beliefs, and planning and achieving life goals (Coleman & Hendry, 1990). This suggests that in adolescence, parents and peers are each support agents with influence that differs in a domain-specific fashion, with young people relying on each in relation to specific issues and concerns. One of the important changes with increasing age, however, concerns children's attitudes toward help seeking. Seeking emotional reassurance or instrumental aid is natural and encouraged in young children, but adolescents are likely to resist help seeking if doing so is regarded as a threat to self-efficacy or perceived competence (Robinson & Garber, 1995). The combination of teenagers' reliance on their parents for support and the need to perceive themselves as self-reliant helps to account for the mixed signals that parents (and, to a lesser extent, peers) receive during this period of life and the ease with which adolescents' support needs within the family can be misunderstood.

With increasing age, children not only experience changes in their help-seeking attitudes but also achieve access to a greater variety of sources of social support outside the family. Infants and young children are influenced by the supportive or nonsupportive social environments of out-of-home care, of course, from an early age (Cochran & Brassard, 1979; Feiring & Lewis, 1988, 1989; Votruba-Drzal, Coley, & Chase-Lansdale, 2004). Child care experiences affect young children directly through the security of the relationships they develop with providers, the quality of

the child care environment, and the developmental guidance providers offer. Child care affects young children indirectly as providers monitor the child's well-being, offer support and information to parents, and provide referrals (such as to mental health services or community agencies) from which children and parents can benefit (Thompson, Laible, & Robbennolt, 1997). In these ways, child care can be a significant source of social support early in life, contingent to a great extent on the quality of care. Entry into school further widens children's extrafamilial natural support networks through both curricular opportunities (such as relationships with teachers, counselors, and peers) and extracurricular activities (such as in sports, clubs, and service programs; Asp & Garbarino, 1983; Lynch & Cicchetti, 1997; Rose et al., 2003). Teachers can be especially important sources of social support because they, like child care providers, may be the first to identify problems that emerge in a child and can create a bridge between children and their parents with professionals who can offer assistance. Moreover, well-trained teachers can sensitively assess the constellation of difficulties a child exhibits by realizing, for example, that classroom behavior problems and emotional difficulties may be an indication of child maltreatment at home (Meehan, Hughes, & Cavell, 2003; Thompson & Wyatt, 1999). In adolescence, workplace and community associations further broaden potential sources of social support as young people achieve greater independence from family networks.

In all of these contexts, the emergence of extrafamilial sources of social support offers avenues of potential aid that are not entirely contingent on parental cooperation. Equally important, children and youth actively construct and maintain these networks. With increasing age, for example, they choose many of the activities in which they participate and the adults and peers with whom they affiliate. There are also significant developmental changes in the social skills that enable children to maintain affiliations that they experience as supportive. With increasing age, for example, children become more skilled at taking active initiative in maintaining the relationships that matter to them, and they develop the social skills required to make these relationships mutually rewarding. Furthermore, children of all ages are also active construers of the support likely to be provided by different partners in their social settings (Furman & Buhrmester, 1985, 1992; M. Reid, Landesman, Treder, & Jaccard, 1989). They readily distinguish the partners who are likely to offer aid and the situations in which these partners are likely to be most helpful, and this helps them to enlist assistance when it is needed.

The role of children as constructors, maintainers, and construers of their natural networks of social support is crucial to understanding the role of social support in developmental psychopathology. Children who experience psychological difficulty have considerable need for supportive relationships, but their clinical problems may also undermine the skills required to constructively maintain those associations. Indeed, children with conduct disorders, ADHD, and other clinical problems may, because of their behavioral difficulties, repel or drain potential support providers of helpful solicitude. Furthermore, children who are depressed, traumatized, or experience other affective disorders may have difficulty perceiving potential help providers as being genuinely supportive and, for this reason, may reject assistance that is offered. Thus, somewhat ironically, at the same time that they are in greatest need of natural sources of social support, children with clinical problems may be least capable of creating or maintaining the relationships that will provide them with aid or of perceiving assistance from the interpersonal sources from whom it may be most readily available. This constitutes a formidable challenge for those who seek to ally natural support networks in therapeutic efforts and is a challenge to formal helpers (e.g., counselors and therapists) who must also overcome these difficulties in their efforts to offer aid.

SOCIAL SUPPORT AND PSYCHOLOGICAL WELL-BEING

At its best, social support provides recipients with emotional understanding, instrumental aid, counseling and guidance, material resources, and/or referrals to other sources of assistance. Viewed in this light, there are at least two ways that social support mediates the impact of stress for individuals at risk (Barrera, 1986; Cohen & Wills, 1985; House, Umberson, & Landis, 1988; Vaux, 1988).

First, social support can be *stress-preventive*. Social support invests its recipients with the material and psychological resources that foster positive development and thus prevent many stresses from occurring. These resources include healthy practices (e.g., exercise, diet, socializing), self-esteem and a sense of belonging, social competencies and coping strategies, access to emergency aid, social monitoring, specific skills, and other benefits that arise from the examples, encouragement, and/or material aid of social partners. Having these resources reduces the likelihood that recipients will experience

physical or psychological difficulty owing, for example, to poor health, social isolation or rejection, or hopelessness. The stress-preventive functions of social support are especially important to children who rely so significantly on others for their well-being; they highlight how the material and psychological resources of parents are instrumental to preventing many of the difficulties that their offspring might encounter. Parents who are warm and nurturant, support the positive self-esteem of offspring, encourage constructive social competencies, and foster academic success help to reduce stress in children by strengthening socioemotional competencies and self-confidence. Moreover, partly through parents' social networks, children have access to other support agents (e.g., teachers, extended family, neighbors, coaches, mentors, and peers) who also reduce stress by promoting skills and resiliency. In this respect, especially for children at risk, social support is one of the most important protective factors within the broader constellation of risks and vulnerabilities that children experience.

Second, when stress occurs, social support can be *stress-buffering*. In other words, the material and psychological resources available through supportive relationships diminishes the impact of stressful events by enhancing coping. Clinical studies have shown that social support is associated with a reduction of the effects of disease pathology and psychological distress on stressed individuals, contributing to less severe symptomatology, quicker recovery, enhanced coping, and diminished long-term sequelae (e.g., Cassel, 1974; Cobb, 1976; Cohen & Wills, 1985). This can occur by altering (e.g., by making more constructive or realistic) recipients' appraisals of stressful events, enhancing knowledge of coping strategies, providing useful information or instrumental aid, and supporting self-esteem and perceptions of self-efficacy. Social support as a stress buffer is important to children who lack the more sophisticated knowledge, appraisal skills, and coping capacities of adults and who are thus more vulnerable to the psychological challenges posed by negative life events. In this sense, it is even more important to children to have someone who is psychologically alongside them when encountering stressful events because of the assistance that an older individual can provide in effective coping.

There is recent evidence from molecular genetics research that social support can buffer the impact of stress and biological risk on children's vulnerability to psychopathology. A recent study by Kaufman and colleagues (2004) showed that among children with a history of maltreatment and with a genetic vulnerability to depression,

those without social support had the highest depression ratings, whereas those with access to positive social supports exhibited only minimal increases in their depression scores. These findings illustrate the interaction of genes and environment in the development of vulnerability to psychopathology and the influence of social support as a potential moderator of the genetic vulnerability to clinical problems (see Cicchetti & Blender, 2004).

Quite often, the stress-preventive and stress-buffering functions of social support have simultaneously protective effects on psychological well-being. One important example is peer support in childhood. Developmental and clinical theorists, such as Sullivan (1953), have long emphasized how peer support shares the stress-preventive and stress-buffering characteristics of adult social support; this is reflected in current views of the association between peer relationships and developmental psychopathology. In their 1995 review, for example, Parker, Rubin, Price, and DeRosier described how children's and adolescents' friendships can contribute to enhancing self-esteem and positive self-evaluation, provide emotional security, offer a nonfamilial context for intimacy and affection, give informational and instrumental assistance, and provide companionship and stimulation. These benefits accrue through the influence of at least three features of peer relationships: peer acceptance (or popularity), number of reciprocal friendships, and friendship quality. Each of these features independently and collectively improves children's and adolescents' concurrent life satisfaction and feelings of self-worth (Parker & Asher, 1993). In these respects, then, peer relationships appear to have social support features similar to those noted earlier for adult relationships. Moreover, peer social support can have enduring influences. A longitudinal investigation of preadolescent friendship and adult adjustment found, for example, that peer group acceptance and friendships in the fifth and sixth grades were significantly predictive of adult life status, perceived competence, and psychopathology 12 years later. Peer group acceptance and friendship made unique contributions to psychological well-being: Having a reciprocal friendship in fifth or sixth grade showed a moderately strong association with general self-worth 12 years later, even when preadolescent levels of self-competence were controlled (Bagwell, Newcomb, & Bukowski, 1998).

In light of these influences of social support on stress, the absence or deterioration of social support can be associated with enhanced stress and poorer coping: Individuals who are isolated or rejected, or who experience the withdrawal of others' support, are more prone to difficulty. As

we shall see in the section that follows, the absence of social support is, at times, implicated in the etiology of child psychopathology and the maintenance of children's problems over time. The enhancement of social support (especially the dimensions of support most relevant to a child's problems) is also associated with the remediation of symptomatology. Each of these processes underscores the stress-preventive and stress-buffering influences of natural sources of social support in everyday life.

The association between social support, stress, and psychological well-being is complicated, however, because enhanced stress can sometimes provoke the deterioration of social support for troubled individuals. Unfortunately, this is what often occurs when adults and children encounter difficulty. Although people often seek supportive partners when they are stressed, it is also true that stressors diminish social support as they cause individuals to withdraw from others because of their circumstances (e.g., job loss, divorce), their incapacity (e.g., hospitalization, emotional turmoil), or their humiliation and feelings of vulnerability arising from stressful events (Shinn, Lehman, & Wong, 1984; Vaux, 1988). Moreover, potential sources of support may withdraw from individuals under stress because the behavior of the recipient is disturbing (e.g., psychological disorders, domestic violence, sexual abuse of children), the problems of the recipient are emotionally challenging or overwhelming (e.g., terminal diagnosis; loss of a family member), or potential support providers are undermined by the same circumstances as the recipient (e.g., poverty, single parenting; Belle, 1982; Fischer, 1982; Wortman & Lehman, 1985). More generally, potential support providers may withdraw from troubled individuals because of the sheer emotional drain of providing one-way assistance to very needy individuals (Fisher et al., 1982; Shumaker & Brownell, 1984). The self-protective withdrawal of potential helpers derives from the difficulties of providing assistance to individuals who need so much. Stress may be associated with diminished (rather than enhanced) social support, therefore, because the circumstances associated with stress may cause potential recipients to be unable or unwilling to receive aid and potential help providers to withdraw. Children who have been abused may lose access to potential support agents, for example, because of their anguished withdrawal from social interaction with familiar people, a parent's efforts to isolate them from others, the deterioration of social relationships owing to the emotional impact of their abuse on social competence, or others' sense that something is very wrong with the family (Cicchetti & Bukowski, 1995; Ro-

gosch & Cicchetti, 1994; Salzinger, Feldman, Hammer, & Rosario, 1993). Emotional engagement itself can offer less positive support than might be expected. As the literature on expressed emotion suggests, high levels of emotional concern can too easily become intrusive or critical and thus damaging, especially when the emotional intensity interacts with an individual's temperamental or biological vulnerabilities (Brown, Birley, & Wing, 1972; Caspi et al., 2004; Hooley, Orley, & Teasdale, 1986; Miklowitz, Goldstein, Nuechterlein, Snyder, & Mintz, 1988; Rogosch, Cicchetti, & Toth, 2004). One study reported that toddlers' behavior problems were predicted by differences in the expressed emotion of mothers and fathers in families where maternal depression had characterized family life since the child's birth (Rogosch et al., 2004). Ironically, the individuals most in need of social support may find it least available within their natural social networks.

Childhood and adult depression also illustrates how social support may be least available to individuals who urgently need it, owing to the reactions of potential benefactors and recipients of support (see reviews by Cohen & Wills, 1985; Coyne & Downey, 1991; Robinson & Garber, 1995). The anhedonia of depressive symptomatology is typically accompanied by social withdrawal together with irritability and hostility, passivity, self-denigration, dependency, and a sense of helplessness and hopelessness. Not surprisingly, the demands these symptoms impose on close relationships can cause others to withdraw and avoid contact, which, in turn, confirms the depressed person's perceptions of being rejected by others and of relationships being unreliable (Coyne, Burchill, & Stiles, 1991; Coyne & Downey, 1991). Depression is thus associated with smaller social networks, fewer close relationships, and diminished perceptions of others' support by the depressed adult, and the same associations have been found for children and youth. DuBois, Felner, Brand, Adan, and Evans (1992), for example, found a negative association between social support and psychological distress 2 years later in young adolescents, with initial levels of distress as well as other sources of stress controlled. They also found evidence that distressed youth acted in ways that inadvertently reduced their access to social support and increased the stress of daily experiences.

In short, the association between social support and stress is complex. Support may be related to the prevention of stress, so that individuals in supportive networks encounter difficult circumstances less often than do those in small or disconnected networks. Support may also be a stress buffer such that heightened social support

is associated with reduced levels of stress. However, although stress may lead to a mobilization of support networks and thus a reduction of stress, social support and stress may also be negatively associated because of the impact of stressful events on a person's access to and willingness to enlist supportive assistance. These complexities in the association between social support and stress suggest caution in studying the empirical relations between them and emphasize the importance of studying their relations over time in prospective longitudinal research designs.

Dimensions of Social Support and Psychological Well-Being

As a predictor of psychological functioning, social support can aid adaptive coping (Barrera, 1986; Robinson & Garber, 1995; Thompson, 1995). It is common to think of social support as a function of *social embeddedness*, which indexes the frequency of contact with social network members. Individuals who see others often, especially in large social networks, would be expected to derive many benefits from social contact, whereas social isolation would limit access to the personal and material resources that others can offer to assist in coping with difficulty. Consistent with this view, abusive and neglectful parents have been described as socially isolated and thus lacking the personal guidance, material aid, emotional support, and social monitoring that more typically occurs in well-integrated social networks (e.g., Daro, 1988; Polansky et al., 1981; Seagull, 1987). But social embeddedness is not, in itself, a strong index of the amount of social support that individuals expect, or receive, from their network associates (Barrera, 1986; Cohen & Wills, 1985). Social partners can be helpful or hurtful, and conflict often accompanies support in people's relationships with family members, neighbors, coworkers, and others in the social network. This means that straightforward efforts to increase the size of an individual's social network or enhance the frequency of social contact is unlikely to be an effective enlistment of social support on their behalf, even though this strategy has been common in the prevention of child maltreatment and other areas of developmental psychopathology. Instead, a deeper understanding of the amount or quality of support that is given and received, and the affective quality of social relationships within the network, is necessary.

Clinicians and researchers often focus on two other dimensions of social support: *enacted support* and *perceived support*. The first indexes the frequency of actual help giving in relationships, and the second assesses the individ-

ual's expectations of support from relational partners. Enacted support and perceived support are not, surprisingly, highly associated with each other, and this derives from their complex mutual association and the relation of each to the stressful circumstances in which social support is valuable (Barrera, 1986). People can have confidence in the assistance that is potentially available from others without actually utilizing their aid, which is one reason enacted support and perceived support are not necessarily strongly associated. In addition, social support can be given without the recipient's awareness (e.g., anonymous benefaction). Furthermore, many acts of social support are not perceived as being supportive by troubled recipients. Counseling that causes a person to critically reexamine aspects of his or her behavior, material aid that causes recipients to feel indebted or humiliated, and efforts to reduce another's drinking or other destructive habits may be motivated by genuine supportive concern but are likely to be regarded by recipients as painful, intrusive, or unnecessary.² This is important because it illustrates how recipient reactions to aid, and their effects on providers of social support, can complicate and sometimes undermine helpful assistance to needy individuals and families. It illustrates also how individuals may experience support without perceiving others as supportive or, conversely, may expect little support from network members who are actually striving to provide assistance. It all depends, in part, on individuals' expectations of social support.

Enacted support and perceived support may also be relevant to different features of coping with stress. If individuals are capable of mobilizing their social networks, enacted support may follow the onset of stressful or distressing circumstances, especially if potential helpers are available and willing to provide aid. Perceived support may, in turn, be especially important to subsequent coping, and to stress prevention, because of a sense that others are reliably "on your side." Each are likely to be predictive of

² Although it can be argued that genuinely supportive assistance will be offered in a manner that reduces negative reactions by recipients, it is nevertheless true that obtaining benefits from another—especially when it cannot be reciprocated, is undeserved, or derives from personal need—almost inevitably heightens feelings of indebtedness, failure, and vulnerability in recipients. As we discuss further, recognizing this not only helps to create more realistic expectations concerning the consequences of providing social support (such as in the context of a home visitation program), but also makes more comprehensible the apparently inexplicable rejection of further aid by the recipient that often occurs.

more successful adaptation in difficult circumstances,³ although further research is needed to clarify the relations between enacted support, perceived support, and coping for children and adults.

Perceived support is the dimension of social support that is most strongly related to psychological well-being in adults and children (Barrera, 1986; Cohen & Wills, 1985; Jackson & Warren, 2000; Sarason, Shearon, Pierce, & Sarason, 1987). This is so because regardless of network size or social embeddedness, confidence in the availability and helpfulness of social partners is crucial to maintaining a sense that assistance is available and the hope that can ensue even in difficulty (this is, in a sense, what is meant by a secure attachment relationship early in life). Moreover, assessments of perceived support are inherently subjective of measures of social support, relying on how individuals appraise the reliability of their social networks, and thus measures of perceived support tap an important feature of emotional coping for individuals under stress. The significance of perceived support as a psychological resource for coping is important, moreover, for intervention strategies. It suggests that rather than seeking to engage troubled individuals in a broader social network or more frequent social interaction as a means of enhancing social support, it is sometimes more important to focus on the person's subjective experience of supportiveness from network associates, perhaps by carefully examining their expectations of support in relation to what they perceive to be provided by others around them.

There are developmental differences in perceived support from different network associates (Furman & Buhrmester, 1985, 1992; Levitt, Guacci-Franco, & Levitt, 1993; M. Reid et al., 1989). In self-report studies, adolescents report expecting less support from their parents than do younger children, and there are similar decreases in perceived support from other family members, such as siblings and grandparents. Expectations of support from peers in-

crease from childhood to early adolescence, but then stabilize or decline in later years. Teachers, by contrast, are rarely regarded as sources of social support. Individual differences in prior social experiences also contribute to differences in perceived support. In a study with African American 4½-year-olds, for example, Anan and Barnett (1999) reported that secure attachment predicted heightened perceived support in these preschoolers and that each variable predicted children's subsequent adjustment, with perceived support mediating the association between attachment and adjustment.

As these developmental and individual differences suggest, perceived support depends, in part, on one's expectations of support from different network associates. Thus, individual differences in perceived support derive, in part, from the quality of assistance that people expect from family members, neighbors, peers, coworkers, and others. There is considerable need for greater understanding of the factors contributing to individual differences in expectations of support because of its relevance to perceptions of support by troubled individuals. Besides the developmental differences noted earlier, for example, how do experiences of stress and the turmoil of psychopathology alter expectations of social support? Do the overwhelming emotional needs of depression and anxiety disorders heighten expectations of support or increase dissatisfaction with perceived support—or both (as studies reviewed earlier seem to suggest)? Or are individuals in turmoil grateful for whatever assistance they can find from their exhausted social networks, as is suggested by Belle's (1982) evocative study of socioeconomically distressed single mothers? Studying questions such as these is important to understanding the social support needs of at-risk children and adults.

As valuable as is perceived support, it is important to note that it does not encompass all of the important features of social support, especially those most relevant to assisting troubled individuals and families. This is because individuals may perceive support from network associates who are otherwise acting in a nonsupportive manner. This is tragically illustrated by Jill Korbin's (1989, 1991, 1995) interviews with mothers convicted of fatal child abuse. These mothers were surrounded by family, friends, and neighbors who were often painfully aware of the bruises, neglect, and other harms inflicted by the mothers on their offspring. But in their efforts to be emotionally supportive, these network associates failed to challenge abusive practices and instead overlooked signs of parental dysfunction, minimized the seriousness of abuse, and offered reassurance about the mothers' good intentions while providing noncritical emotional affirmation. In so doing, of course, they contributed

³The relationship between enacted support, perceived support, and coping is empirically complicated, moreover, by the fact that in correlational studies, (1) troubled individuals may be less capable of viewing others as sources of available support because of their emotional turmoil, (2) individuals in difficulty may be less able to mobilize supportive networks when they are needed, and (3) individuals who experience psychosocial well-being are more likely to be high in perceived support. For these reasons, process models of the relationship between stressful events and various kinds of social support, developed in the context of prospective longitudinal designs and using multiple measures of support (that include, but are not restricted to, subjective evaluations) are necessary in future research.

little to curbing abusive practices or protecting the children, and were thus ineffective in preventing the death of these children. As Korbin (1991, p. 23) noted, "A high level of perceived support sustained, probably unintentionally, these women in their pattern of abusive behavior."

In short, the quantity of social relationships should not be mistaken for the quality of social support. People can be surrounded by a large network of social partners who offer little support or who are emotionally affirming while providing little other assistance to troubled individuals. This is one reason efforts to improve social support by increasing social network size or improving social embeddedness are unlikely to increase enacted or perceived support. In addition, a focus on perceived support highlights the importance of how children and adults with psychological disorders perceive—accurately or inaccurately—the supportiveness of their natural networks and the potential value of interventions that target these social perceptions.

Because social support is not the same thing as network size, it is noteworthy that in some cases, access to only one or a few confidants is sufficient to significantly aid coping under stress (Cohen & Wills, 1985; Gottlieb, 1985). With adults (Brown, 1987; Brown, Adler, & Bifulco, 1988) and children (Pellegrini et al., 1986), the absence of a confiding relationship has been found to significantly distinguish whether individuals under stress developed affective problems or not. For adults, supportive intimacy can be found with a romantic partner or spouse; in the study by Pellegrini and colleagues, it was the absence of a best friend that predicted risk for affective disorders in middle childhood. Taken together, these findings contribute to the conclusion that it is not number but quality of relationships that shapes perceptions of support and, in turn, the benefits of social support for coping with stress.

SOCIAL SUPPORT AND DEVELOPMENTAL PSYCHOPATHOLOGY

It is clear that social support is associated in complex ways with stress and coping. Support can be stress-preventive and it can be a stress buffer when difficulty ensues. Support can be mobilized when stress occurs, but stressful events can also reduce access to support networks and an individual's capacity to receive aid that is offered by others. The importance of perceived support adds further complexity to the association between social support and stress because of how stress can alter a person's awareness of supportive access to helpers.

It follows, therefore, that the association between social support and developmental psychopathology is also complex. In this section, we explore this complexity by distinguishing three phases in the course of psychological disorders. First, we consider how social support, especially its absence, is relevant to the initial development of psychological disorders. This is especially relevant to portrayals of social support as a preventive and buffering agent in stressful circumstances. Second, we examine the role of social support (and its absence) in the maintenance of psychopathology over time, underscoring the importance of social factors in the persistence of psychiatric symptomatology. Finally, we consider social support and the treatment of psychopathology and the alternative avenues that exist for enhancing support as a therapeutic aid.

Social Support and the Origins of Developmental Psychopathology

In light of the stress-preventive functions of social support, it is reasonable to expect that individuals who are socially isolated or are in social adversity in the context of stress would be at enhanced risk of psychological problems. Such people are, in a sense, denied the emotional, material, informational, and other kinds of assistance that companions can potentially provide. The important challenge is to understand the extent to which the lack of social support is crucial, independent of other risk factors, in contributing to risk for developmental psychopathology, and why.

The complexity of developmental processes, the diverse etiological contributions to clinical symptomatology, and the methodological challenges of research in developmental psychopathology together make it difficult to construct causal models linking social support to either healthy or unhealthy functioning. Current theoretical views posit complicated, reciprocal associations among biological, cognitive and emotional, and sociocultural processes that are mutually influential in a dynamic, nonlinear fashion to predict most developmental outcomes (see Cicchetti & Toth, 2003; Cicchetti, Toth, & Maughan, 2000; Dodge & Pettit, 2003; Sameroff & Chandler, 1975; Shonkoff & Phillips, 2000). In such models, both parent-child and peer relationships are typically regarded as primary social influences on development that have both direct and indirect effects on risk for psychopathology. Dodge and Pettit propose, for example, that parenting and peer experiences each mediate between biological predispositions or the sociocultural context and children's vulnerability to chronic antisocial conduct problems. A recent molecular genetics study by Kaufman and

colleagues (2004) indicates that social support may moderate the effects of biological vulnerability and a history of maltreatment on children's proneness to depressive symptomatology. In short, social support is likely not only to have a direct relationship to the development of psychopathology but also to mediate the effects of other risk factors in complex ways.

The social isolation of families who have abused or neglected their offspring, or who are at significant risk of doing so, is the most extensively studied condition in which the absence of social support is believed to contribute to the development of psychopathology. In this case, children's risk of pathological development is mediated through their parents' social support. Many researchers have concluded that parents who abuse or neglect their offspring lack significant social connections to others in the extended family, neighborhood, and broader community and to social agencies that can provide assistance (e.g., Daro, 1988; Garbarino & Sherman, 1980a; Polansky et al., 1981; Seagull, 1987; Straus et al., 1980; see Thompson, 1995, for a review). As a consequence, their treatment of offspring is likely to remain undetected, there are few interpersonal resources to which parents can turn when they are stressed, and the ways that social connections with potential helpers can buffer the effects of stress, promote healthy behavior, and socialize positive parenting are less influential.

An extensive review of this research by Thompson (1995) yields a fairly complex picture of the association between social isolation and child maltreatment. Three conclusions from his review are important to this discussion of social support and developmental psychopathology. First, in most studies, the social isolation distinguishing abusive or high-risk parents consists of their smaller social networks or their more limited social contacts with network members (i.e., limited social embeddedness). Parents at risk of child abuse know fewer people and see them less often, compared to other parents in similar circumstances. But research findings are inconsistent about whether at-risk or abusive parents experience significant deficits in enacted support or perceived support from their network associates. A study by Lovell and Hawkins (1988) is typical, in which abusive mothers reported that very few of their network associates provided practical help with child care or parenting responsibilities, but mothers reported enjoying seeing nearly 80% of these companions very much and reported that they could "share their thoughts and feelings frequently" with nearly 50% of them. Like the fatally abusive mothers studied by Korbin (1989, 1991), perceived

support from network associates was often satisfactory even though the social support mothers received did not significantly reduce abuse potential. Thus, on the most important dimension of social support for psychological well-being—perceived support—there are often negligible differences between maltreating parents and those who are nonabusive, even though the social networks of maltreating parents are smaller and less supportive in other ways.

Second, there are subgroups of maltreating parents who experience significant social isolation for specific reasons. Polansky and his colleagues (Polansky, Ammons, & Gaudin, 1985; Polansky et al., 1981; Polansky, Gaudin, Ammons, & David, 1985) have studied neglectful mothers who consistently reported feeling greater loneliness and lack of neighborhood support compared with socioeconomically comparable nonneglectful mothers. Polansky has described an "apathy-futility syndrome" consisting of a passive, withdrawn demeanor coupled with emotional "numbness," limited competence, distrust of others, retreat from social contact, and verbal "inaccessibility" to others that also makes them hard to reach socially (Gaudin & Polansky, 1986; Polansky & Gaudin, 1983). In Polansky's view, the social isolation of these mothers derives from their inability to develop and maintain supportive social ties owing to character disorders, deficient social skills, and difficulties in coping adaptively with life stress. In a sense, their neglect of offspring is part of a general syndrome associated with their broader neglect of social connections. By contrast, Garbarino has described a different kind of "social impoverishment" of families in neighborhoods that experience heightened rates of child maltreatment (Garbarino & Kostelny, 1992). By comparing neighborhoods with higher-than-expected child maltreatment rates (based on sociodemographic predictors) with neighborhoods with lower-than-expected maltreatment rates and using informants in each community, Garbarino has sought to characterize the neighborhood conditions associated with child abuse and neglect (Garbarino & Sherman, 1980a, 1980b). He found that mothers in higher-risk neighborhoods reported receiving less assistance from neighbors, finding fewer options for child care, and generally perceiving the neighborhood as a poorer place for raising children. On other assessments related to social support, such as perceptions of sources of potential assistance, the friendliness of neighborhoods, and recreational opportunities, however, mothers of higher-risk and lower-risk neighborhoods did not differ. By contrast with the characterological problems of the neglectful mothers studied by Polansky and his colleagues, therefore, the mothers

of higher-risk neighborhoods studied by Garbarino lacked important features of social support owing to the diminished social resources of their neighborhoods and the diminished human capital of their communities.

Third, studies like these and others indicate that social isolation is not a homogeneous phenomenon, and consequently the reasons for social isolation are diverse in families at risk for child maltreatment (Thompson, 1995). For some, such as Polansky's neglectful mothers, isolation may derive from social marginality attributable to limited social and coping skills in the context of stressful life circumstances (see also Seagull, 1987). For others, such as Garbarino's higher-risk neighborhood residents, it arises from the impoverishment of social capital in difficult neighborhoods that may also be dangerous settings for children and that breed social insularity and distrust (see also Lynch & Cicchetti, 1998). For some, social isolation may be actively sought as a means of concealing abusive practices. For others, isolation may result from difficult circumstances that rob adults of the time or energy required to maintain social networks, or create feelings of humiliation and vulnerability and a desire to be left alone. And a significant proportion of high-risk families do not feel socially isolated at all, but are instead satisfied with their social interactions with a small network of close associates who provide emotional support but do not seem to constrain abusive or neglectful practices. "Social isolation," when it is apparent, can have diverse causes.

The multifaceted causes of social isolation in families at risk for child maltreatment is important for at least two reasons. First, these studies indicate that social insularity may be a significant factor in the origins of child maltreatment for some families, especially when the causes of social isolation derive from psychological problems in parents, difficult or dangerous neighborhood conditions, or active efforts to conceal abusive practices. In these circumstances, the absence of significant social connections increases risk for child maltreatment because there are few from outside the family who can provide emotional support or material aid or monitor parental conduct, especially in the context of life stress. However, it is unwarranted to inclusively generalize this portrayal of abusive families. For many other families, social isolation does not appear to be etiologically relevant because abusive practices occur in the context of active social networks from which parents derive emotional support. Social isolation is not necessarily implicated in child maltreatment—and perceived support is not necessarily a buffer against abusive parenting. Second, the multifaceted causes of social isolation are relevant to intervention. Strategies for enhancing social sup-

port for at-risk families who are socially isolated must also be multifaceted. They may require, for example, social skills training (Gaudin, Wodarski, Arkinson, & Avery, 1990–1991), improving recipient reactions to receiving assistance (Tracy, Whittaker, Boylan, Neitman, & Overstreet, 1995), incorporating new support agents into natural social networks, or other approaches depending on the causes of social insularity. As we discuss in a later section, when enlisting social support in clinical treatment, one size does *not* fit all.

Social support and social isolation are experienced not only by families, but within families as well. In particular, children may be deprived of social support in families characterized by marital conflict, domestic violence, parental affective disturbances, child maltreatment, or other problems. Extensive research literature documents the risks for the development of internalizing and externalizing problems for children growing up in disturbed family environments (Thompson & Calkins, 1996; Thompson, Flood, & Lundquist, 1995). Children in homes characterized by marital conflict, for example, seek to reestablish the emotional security they have lost by intervening in parental arguments, monitoring parental moods, and otherwise striving to manage their emotions in a conflicted home environment (Cummings & Davies, 1994, 1996; Davies & Forman, 2002; Grych & Fincham, 1990; Katz & Gottman, 1991). As a consequence, they show heightened sensitivity to distress and anger, tend to become overinvolved in their parents' emotional conflicts, have difficulty regulating the strong emotions that conflict arouses in them (in a manner resembling "emotional flooding"), and exhibit other indications of internalizing problems. The work of Shaw and his colleagues has shown how the early development of conduct problems in young children derives from the interaction of the child's temperamental vulnerability with maternal rejection and depression, parental conflict, and other indicators of family difficulty (Owens & Shaw, 2003; Shaw, Miles, Ingoldsby, & Nagin, 2003). Research on maternal depression shows, as earlier indicated, how the family environment presents children with overwhelming emotional demands deriving from the caregiver's sadness, irritability, helplessness, and guilt-inducing behavior, which contributes to children's enmeshment in the emotional problems of the adult and their own vulnerability to internalizing problems (Ashman & Dawson, 2002; Cummings & Davies, 1994, 1996; Zahn-Waxler & Kochanska, 1990).

These troubled family environments are deficient in much more than social support, of course. Children are also subjected to heightened parental negative affect, fam-

ily conflict, and other challenges to their emotional well-being. The relevance of social support is highlighted, however, in interventions in which children are offered the assistance of adults outside the family to aid in their emotional coping (Sandler, Miller, Short, & Wolchick, 1989). In a study by Blanchard, Molloy, and Brown (1992; cited by Beeman, 2001), for example, children living in violent homes reported that the best support was from a caring adult located nearby with whom the child could talk about family conflict. Although considerably more research is needed to examine the effects of extrafamilial social support on children's coping with family problems, studies like these suggest that access to social support can help to buffer the effects of family difficulty.

As children mature, social support may be obtained from peer relationships as well as family networks, and, conversely, vulnerability to problems may be enhanced by peers as well as family members. Positive peer relationships are likely to be protective influences, therefore, in preventing and buffering stress, and peer rejection and relationships with deviant peers may contribute to the development of childhood and adolescent depression and conduct problems. Although peer experiences are more likely a mediator or moderator of other risk factors than a direct causal agent for most forms of childhood psychopathology, there is evidence that peer relationships can assume a significant role in their development. One large, prospective longitudinal study that followed more than 500 randomly selected children from preschool through early adulthood found that, as early as preschool, exposure to aggressive peers predicted later aggressive behavior (Sinclair, Pettit, Harris, Dodge, & Bates, 1994). In another longitudinal study, Gazelle and Ladd (2003) found that the combination of anxious solitude (an index of individual vulnerability) and peer exclusion predicted levels of depressive symptoms in a sample of 388 children studied from kindergarten to fourth grade. There is evidence for the stress-buffering effects of positive peer relationships as well. In the prospective longitudinal study by Dodge, Pettit, Bates, and their colleagues, peer acceptance moderated the effects of low SES, high family stress, single-parent status, and violent marital conflict on the development of externalizing behavior in early grade school (Criss, Pettit, Bates, Dodge, & Lapp, 2002). In the same study, peer acceptance and friendship overlapped in their moderation of the effects of harsh discipline on the same outcomes. These positive effects of peer relationships remained even when the researchers controlled for child temperament and social information-processing skills. Of course, the influence of peer relationships on risk for

psychopathology is as complex as is the influence of parental social networks. Indeed, in some cases, the same friendships that protect children from internalizing problems, such as depression, may enhance antisocial behavior (Nangle, Erdley, Newman, Mason, & Carpenter, 2003).

Social Support and the Maintenance of Developmental Psychopathology

Psychological disorders have multifaceted origins, of course, arising from the interaction of biological vulnerability, ecological demands and stresses, cognitive constructions, and other influences. The absence of social support, especially in the context of conflict in close relationships, adds further risk to the development of internalizing and externalizing disorders, and the availability of social support can, in turn, help to buffer the onset of clinical symptomatology. Social support and its absence are relevant also to the persistence of symptomatology over time. In other words, once clinical problems have developed, their maintenance may be associated with continuing social adversity and social isolation. Several research fields suggest how this may be true.

Children with anxiety disorders are highly vigilant for and hyperresponsive to situations associated with fearful stimuli. They interpret everyday situations in ways that exaggerate potential threat, are acutely sensitive to their own visceral signs of fear arousal, and become preoccupied with their negative emotion (Vasey & Ollendick, 2000). Not surprisingly, they are challenging for caregivers to help, but research indicates that the efforts of parents to be supportive may exacerbate rather than remedy anxious symptomatology (Thompson, 2001; Vasey & Dadds, 2001). Many parents of anxious children respond sympathetically and protectively to the fear expressed by their offspring, assisting the child in avoiding the fear-provoking event but, as a consequence, offering few opportunities to master the anxiety (Dadds, Barrett, Rapee, & Ryan, 1996; Gerlsma, Emmelkamp, & Arrindell, 1990). This is more understandable in light of studies showing an intergenerational family history for anxiety disorders, suggesting that anxiety is learned in families as part of the shared environment and that parents may thus become anxious in situations in which their offspring are also fearful (Eley, 2001). Thus, a child who responds to an anticipated encounter with a fear-evoking event with screaming, tantrums, hiding, and aggressive resistance offers powerful incentives for adults to accede, and if the adult does so and the child subsequently calms down, each partner is negatively reinforced for behavior that helps to perpetuate anxious symptomatology

(Vasey & Ollendick, 2000). At the same time, parents may be worried about the effects of anxious pathology on the child's capacities to act in a socially and developmentally appropriate manner, and thus parental overprotectiveness may be coupled with criticism and rejection (Gerlsma et al., 1990).

Thus, childhood anxiety disorders are likely to be accompanied by troubled family relationships. They are troubled by aversive encounters focused on the child's efforts to avoid fear-provoking events that are inadvertently reinforced by parents' efforts to be supportive and helpful. They are troubled also by the parent's mixed response to the child's behavior—overprotective but also critical—that contributes to parent-child relationships of insecurity and uncertainty. It is important to note that parental behavior in these instances is well-intentioned: Adults are striving to provide social support, even though their efforts inadvertently reinforce anxious symptomatology in their children (Thompson, 2001). One reason for family difficulty is that the emotional support offered by parents does not contribute to alleviating anxious fear or symptomatology.

The development of antisocial behavior is another example of how family processes and child characteristics combine to create a social context that contributes to the maintenance of psychopathology. The well-known work on coercive family processes of Patterson and his colleagues (Patterson, 1982, 1986; J. B. Reid, Patterson, & Snyder, 2002) illustrates specific pathways by which parents may inadvertently foster difficult relationships between themselves and their children or adolescents. As Patterson has evocatively shown, antisocial behavior in children is maintained by parents through their responses to child misconduct. By initially resisting the bad behavior of offspring and then acceding when children escalate their aversive conduct, parents provide powerful negative reinforcement for bad behavior. Patterson's longitudinal studies have shown how such coercive interpersonal processes become generalized by children beyond the family and contribute to the development of antisocial behavior. Although parental practices within these families are not motivated by socially supportive intentions, this work illustrates the ways that aversive parent-child interactions contribute to the development and maintenance of psychopathological conduct through relational influences that victimize the entire family.

Another illustration of the influence of social support in the maintenance of clinical problems is the well-developed research literature linking peer relationship problems and childhood loneliness (see Asher, Parkhurst, Hymel, &

Williams, 1990, for a review). Several recent studies have explored the associations between peer relationships and depressive symptoms in children (e.g., Boivin, Hymel, & Bukowski, 1995; Boivin, Poulin, & Vitaro, 1994; Burks, Dodge, & Price, 1995; Nangle et al., 2003; Oldenburg & Kerns, 1997). Nangle and his colleagues, for example, found that a fully mediational model of the influence of peer relationships on children's loneliness and depression was warranted in their study of 193 third- through fourth-grade boys and girls. In this study, loneliness was the gateway through which peer relationships influenced the development of depression. However, friendships also buffered children from depressive symptomatology. The influence of popularity, or peer acceptance, was completely accounted for by the fact that peer acceptance temporally preceded friendship, suggesting that more popular children were likely to have both larger friendship networks and better relative quality of peer relationships. The researchers concluded that before adolescence, "the mutuality that is unique to friendships appears to be critical" (p. 552). Peer rejection is important not only to the development of depressive symptomatology but also to its maintenance over time, as children without friendships are likely to continue to feel lonely, self-deprecating, and isolated in their peer networks.

Social Support and the Treatment of Psychopathology

Social support is important to developmental psychopathology not only because of its contribution to understanding the etiology or maintenance of pathological symptomatology, but also because of its promise for pioneering avenues for therapeutic assistance. The core features of social support—counseling and guidance, emotional nurturance, information, skill acquisition, and sometimes material aid—are components of successful therapeutic efforts in all theoretical modalities. Whether in the context of individual therapy sessions, peer counseling, group therapy, parent education or parent support groups, therapeutic pre-school programs, crisis counseling, or other therapeutic avenues, social support is an almost inescapable element of successful clinical intervention. Thus, understanding the nature of social support as well as obstacles to its efficacy in promoting psychological well-being and conditions that foster perceptions of support in troubled individuals are each important to successfully enlisting social support in therapeutic efforts. In addition, just as social support is incorporated into most forms of psychological treatment, it is

also a central feature of prevention efforts to avert psychological problems or their recurrence. Social support is a contributor to long-term adaptive functioning as well as immediate assistance to individuals and families in need.

Despite its ubiquitous contribution to therapeutic endeavors, incorporating social support in prevention and intervention strategies presents significant challenges. The forms of social support that are most helpful to individuals experiencing psychological distress are not self-evident, and, as we have seen, not all social support efforts are effective in achieving therapeutic or preventive goals. These are crucial considerations because of the many ways that well-intentioned supportive efforts can be rendered ineffective in changing destructive behaviors, fostering psychological well-being, or accomplishing therapeutic goals. Earlier in this chapter, we considered examples of how the emotional support of family and friends did not prevent troubled mothers from committing fatal child abuse, and how parental efforts to respond sympathetically and protectively does not enable offspring with anxiety disorders to master their fears. To be effective, in other words, the purposes and functions of social support must be strategically considered within a broader array of therapeutic efforts, keeping in mind that social support should include not only emotional sustenance and counseling but also reeducation, behavioral change, and monitoring the well-being of those it is intended to assist. In the following section, we consider three distinct interventions that purposefully incorporate aspects of social support to achieve particular treatment goals. First, we describe a treatment for depression that focuses almost exclusively on the social aspects of the disorder. Originally developed for adults, interpersonal psychotherapy has been adapted for adolescents because of the salience of relationships in adolescent development as well as the time-limited nature of this intervention (Mellin & Beamish, 2002; Mufson & Moreau, 1999). Next, we look at approaches that attempt to teach children to help each other in social situations as a means of enlisting social support from peers in developmental therapy. Finally, we briefly discuss a family support program that helps families whose children have Bipolar Disorder and that directly addresses a dimension of iatrogenic emotional engagement, expressed emotion (EE).

As we have noted, nearly all psychotherapy approaches rely on social support in the relationship between the therapist and the patient, and much of therapeutic content focuses on improving personal relationships. Interpersonal psychotherapy (IPT) is based on the premise that problems in relationships are important components of the maintenance

of depressive symptoms. Interpersonal psychotherapy for adolescents (IPT-A) uses a three-phase, time-limited approach to help adolescents explore the impact of the interpersonal aspects of one or two problem areas on significant relationships (Mellin & Beamish, 2002; Mufson & Moreau, 1999; Mufson, Moreau, Weissman, & Klerman, 1993). Adolescents with Major Depressive Disorder or Dysthymia identify one or two problem areas from a group of five interpersonal concerns (i.e., grief, role disputes, role transitions, interpersonal deficits, or single-parent families). Specific strategies are recommended for each problem area to help adolescents express feelings, use the therapeutic relationship to increase awareness and understanding, and, ultimately, change their behavior in interpersonal situations. For example, the interpersonal deficits problem area identifies social isolation, unfulfilled social relationships, and chronic depression as targets for exploration of past relationships. In addition to exploring previous relationships and behavior patterns, the therapist provides support for the adolescent to change behavior in the interpersonal context. In a study of 71 Puerto Rican adolescents between the ages of 13 and 17 who were diagnosed with Major Depressive Disorder, Dysthymia, or both disorders, interpersonal psychotherapy and cognitive behavioral therapy were both more effective in reducing symptoms of depression when compared with a wait-list control group, and 82% of the IPT participants were able to function in an adequate range at posttreatment, as measured by scores on a depression inventory (Rossello & Bernal, 1999).

Another approach to enlisting social support to remediate clinical problems is to engage natural helpers. For children and adolescents, this usually means providing training and supervision to peers who are then expected to help classmates or friends with needs. The goals of such strategies may be to increase the total number of peers who interact with the target child or to teach the target child social skills that will help her or him to attract more friends. Enlisting healthy, socially skilled peers to help children or adolescents who have behavioral or emotional disorders or who are at risk for the development of such disorders has intuitive appeal because of the potential to address both of those goals. However, as we have learned throughout this discussion, what appears simple and straightforward is often deceptively so. Lewis and Lewis (1996) identified several concerns with involving peers in helping each other. Most notably, in programs without careful role definitions and professional supervision, young people who are motivated by a desire to help others may

find themselves in situations that require significantly more training, expertise, and maturity than they have. Lewis and Lewis focused their analysis on risks to peer helpers in programs enlisting peer support for children at suicidal risk, and they reported findings from a descriptive study of Washington schools indicating that suicide rates were higher at schools where peer helpers were not supervised by professional counselors. As we note later with respect to home visitors, the potential advantages of enlisting natural supporters to aid troubled children or families must be balanced by their limitations in expertise and capability.

Behavioral theory suggests that designing interventions with carefully defined target behaviors and narrowly focused strategies is likely to avoid some of the ambiguity of more general supportive or mentoring approaches and provide more precise guidance about what works and what does not work. Consistent with this view, one group of researchers (Christopher, Hansen, & MacMillan, 1991; Guevremont, MacMillan, Shawchuck, & Hansen, 1989) trained 7- to 9-year-old children in specific social skills and rewarded them for playing with identified classmates. Same-sex peers were trained in initiating, responding to refusals, maintaining interactions, and responding to negative behavior. Each was then paired with a socially isolated, dysphoric child, and rewarded for playing with that child during one daily recess. The intervention resulted in an impressive increase in positive social interactions. The improvement in peer interactions for the target children occurred with both the designated helpers and also with other classmates, and the levels of positive interactions were comparable to those of social comparison children in the same setting. The treatment gains increased at a 4-month follow-up (Guevremont et al., 1989). In a similar study that targeted three socially isolated, dysphoric children, the researchers increased the training for peer helpers and achieved similarly promising results. Gains in positive interactions were maintained at the 4-month follow-up, and the positive effects generalized to situations when the intervention was not used. In addition, there was no evidence of negative impact of social support on the helpers (Christopher et al., 1991).

Interventions designed particularly for family members, especially parents, are often part of the therapeutic endeavor when children and adolescents experience psychopathology. Families are the primary source of support for children, and the quality and effectiveness of the support family members provide to children with clinical problems is crucial to the child's healthy adjustment. As we have seen, however, not all efforts to enhance social support are helpful; indeed, emotional support may not be effective in

remediating children's problems in some situations. In fact, the parent's emotional engagement may have negative effects in certain circumstances. For example, children's emotional or behavioral difficulties may lead to heightened criticism and hostility toward the child (Hooley & Richters, 1995). Expressed emotion (Hirshfeld, Biederman, Brody, Faraone, & Rosenbaum, 1997a) is an index of parental attitudes of criticism or emotional overinvolvement in the child's problems that has been studied as a contributor to the onset, maintenance, or relapse of a number of clinical problems, including Schizophrenia (Brown et al., 1972), depression (Hooley, Orley, & Teasdale, 1986), Bipolar Disorder (Miklowitz & Goldstein, 1997), behavioral inhibition (Hirshfeld et al., 1997a, 1997b), and Conduct Disorder (Calam, Bolton, & Roberts, 2002; Caspi et al., 2004; Rogosch et al., 2004). Family support or treatment components have been designed to include a specific focus on EE as a way of improving the quality of social support for young people with clinical problems. The RAINBOW treatment protocol, for example, is a child- and family-focused cognitive behavioral therapy for children with Bipolar Disorder that addresses the intense personal demands of raising a child with this disorder in an effort to decrease the potentially harmful effects of EE (Pavuluri et al., 2004). Elements of this program include encouraging family members to distinguish helpful from unhelpful reactions in their efforts to cope with a child who can be difficult to live with, helping parents model appropriate strategies for affect regulation, fostering shared effective problem-solving strategies in which parents and target children jointly participate, assisting children in their efforts to develop successful peer relationships, and identifying other sources of social support. Preliminary conclusions from a study of 34 families participating in this program indicated that symptom severity for children decreased significantly following therapy and parents reported strong satisfaction with the treatment, although there were no family-based measures of the emotional environment (Pavuluri et al., 2004).

Taken together, conclusions from these and other therapeutic interventions that explicitly attend to the social support needs of troubled children and families indicate that when carefully designed and thoughtfully implemented, social support can be an important contribution to therapeutic success. But because social support needs are multifaceted, one feature of the preventive or therapeutic enlistment of social support is that supportive interventions are multifaceted. They should include not only emotional aid and counseling but also information or educational guidance, help with everyday stresses and practical life

skills (such as parenting), economic assistance or job training when it is warranted, and, when children are concerned, counseling and educational assistance. Although services must always be tailored to the needs of recipient families, a broad array of socially supportive interventions is most likely to address the salient needs of multiproblem individuals and families.

There are many examples of intervention programs with blended forms of social support. Gaudin's (Gaudin et al., 1990–1991) Social Network Intervention Project, for example, combines strategies to enhance informal social network support for families identified as neglectful with the assistance of regular volunteer aides, the enlistment of neighborhood helpers, and social skills training to enable family members to better create and maintain supportive relationships. Yoshikawa's (1994, p. 28) review of programs to prevent chronic juvenile delinquency concludes that "interventions combining comprehensive family support with early education may bring about long-term prevention through short-term protective effects on multiple risks." Programs like Childhaven combine quasi-therapeutic full-time day care services with practical parent education, casework support, parent support, family therapy groups, and social agency referrals for troubled families (Durkin, 1986; Miller & Whittaker, 1988). The Committee on Integrating the Science of Early Childhood Development of the National Academy of Sciences concluded an extensive review of the prevention research by finding:

Model early childhood programs that deliver carefully designed interventions with well-defined objectives and that include well-designed evaluations have been shown to influence the developmental trajectories of children whose life course is threatened by socioeconomic disadvantage, family disruption, and diagnosed disabilities. Programs that combine child-focused educational activities with explicit attention to parent-child interaction patterns and relationship building appear to have the greatest impacts. In contrast, services that are based on generic family support, often without a clear delineation of intervention strategies matched directly to measurable objectives, and that are funded by more modest budgets, appear to be less effective. (Shonkoff & Phillips, 2000, p. 11)

To be sure, characterizing the variety of intervention strategies encompassed within these preventive efforts as consistently "socially supportive" threatens to overstretch the boundaries of the social support construct. But these reviews underscore that social support efforts must be multifaceted to effectively address the complex needs of troubled children and families, and that social support interventions must be undertaken in an individualized man-

ner that is responsive to the specific needs of recipients and the specific goals of the intervention effort.

THE CONTINGENCIES OF SOCIAL SUPPORT EFFORTS

In a recent review article, Hogan, Linden, and Najarian (2002) asked, "Social support interventions: Do they work?" Their answer was that current research provides support for the general usefulness of social support interventions, but there is insufficient evidence to conclude which kinds of interventions work best for what problems. Likewise, Heller and Rook (2001) noted in their review of social support interventions that the effective ingredients of supportive interventions are still unknown. The problem in designing the most effective interventions to improve social support and increase healthy functioning in troubled individuals may be even broader. Robinson and Garber (1995) noted that there is currently no coherent theory of how social support should guide intervention efforts. Absent a well-developed and empirically based theoretical portrayal of social support, interventions are often guided by a general expectation that greater social support, usually indexed by increased social ties, is a good thing and will have broadly positive benefits. Unfortunately, this often means that social support interventions are vague and ill-defined and, without specific outcome expectations, sometimes fail to accomplish measurable improvement in the lives of their recipients.

In addition to problems in specifying the most effective ingredients of effective supportive interventions and identifying what interventions work best for what psychological problems (and for individuals of what ages), it is also important to understand the contingencies of social support efforts. In other words, what influences can enhance or hinder the efficacy of social support interventions? At times, thoughtfully designed social support efforts founder because of challenges concerning the needs of support providers, the complex recipient reactions to obtaining assistance from another, cultural factors associated with giving and receiving social support, and the goals of intervention. We consider these contingencies next.

Sources of Support and the Needs of Support Providers

Social support may be obtained from informal helpers (such as friends, neighbors, family members, coworkers, teachers, or classmates) or formal helpers (such as counselors or therapists, home visitors, social workers, or

religious advisors). As earlier noted, each kind of support agent has particular strengths and weaknesses (Gottlieb, 1983, 2000). Relationships with natural social network members benefit recipients because of their convenience and mutuality. Each partner is likely to share congruent values and perspectives, and these relationships are influential because they are likely to be enduring and thus well-integrated into many aspects of the recipient's daily experiences (Cochran, Larner, Riley, Gunnarsson, & Henderson, 1990). But because natural helpers share the circumstances and values of recipients, they may also share their stresses and difficulties and may be less sensitive to, or unwilling to challenge, unhealthy or inappropriate conduct if it is typical for their reference group (such as harsh parenting or substance abuse). Formal helpers do not have these disadvantages because of their professional training, and their helping relationships with recipients are well-defined by their professional role responsibilities. But because they are less well integrated into the lives of recipient families, they may be unaware of many circumstances affecting their well-being. Formal helpers can also have difficulty engaging the consistent cooperation of their clients.

These distinctions between formal and informal sources of support are important for defining the capabilities and needs of support providers. Enlisting natural social networks into social support interventions can be valuable but is constrained by the limitations in expertise and skills of informal helpers. As illustrated earlier when describing efforts to enlist peers to support adolescents at risk of suicide, the ethical responsibility of program designers is to ensure that natural helpers like these are not put into situations that exceed their capabilities and skills, which can easily occur if they are striving to help others who have serious psychological problems (Lewis & Lewis, 1996). Likewise, volunteer home visitors have much to offer social support programs because they often share the backgrounds and orientations of recipient families, but most are inadequately prepared to address serious family problems arising from depression, domestic violence, or substance abuse, and they may have difficulty engaging challenging families or following a consistent curriculum (Margie & Phillips, 1999). Although informal helpers are convenient, inexpensive, and often highly motivated, it is unreasonable to expect that their efforts can accomplish as much as professionally trained formal helpers might achieve in similar circumstances, and it is ethically irresponsible to expect them to provide long-term help or to assist individuals with serious problems without training and support. In short, the source of social support enlisted into an intervention de-

fines, in part, the scope of results that might be reasonably expected from the effort.

The source of social support is an important consideration also because offering assistance to troubled individuals can be draining and demoralizing (A. H. Collins & Pancoast, 1976; Shumaker & Brownell, 1984). Recipients are needy but may also be demanding and critical for reasons described in the next section, and providing help in relationships of one-way assistance can be exhausting because support is not reciprocated. Moreover, the relationship between support providers and recipients can be difficult because each may have different goals, with recipients seeking noncritical emotional affirmation and providers also striving for changes in the recipient's behavior and attitudes. They may differ in their views of the recipient's problems and the best solutions to them. Crises may force support providers to focus on immediate needs (urged to do so by recipients) and neglect attention to long-term strategies for building healthy practices. For these reasons, it is common for providers and recipients each to feel frustrated by their relationship and sometimes to experience conflict. The professional training of formal helpers prepares them to cope with these challenges, but informal helpers may be surprised to discover how difficult it is to provide social support, especially if they began doing so with little training or guidance. It is common, therefore, that social support interventions enlisting natural helpers must address the frequent turnover and burnout of their staff, which is reduced but not eliminated when informal helpers are provided with appropriate training, guided supervision, frequent affirmation of the value and importance of what they are doing, and other forms of social support. In designing successful social support interventions involving natural support agents, in other words, it is as essential to train and support the helpers as it is to ensure that appropriate forms of social support are also offered to targeted recipients.

For this reason, integrating the efforts of formal helpers with those of informal helpers in recipients' natural social networks may offer the best opportunities for creating enduring preventive or therapeutic benefits (Froland, Pancoast, Chapman, & Kimboko, 1981; Miller & Whittaker, 1988). The teamwork of formal helpers with members of informal social networks can enable natural helpers to be supported in their efforts while ensuring the skill and expertise that formal helpers can provide. Their integrated efforts can occur in many ways. Formal and informal assistance is harmonized, for example, when a parent support group is organized around a local school or child care program, a perinatal home visitor encourages the company of extended kin during home visits, or a group therapy pro-

gram for adolescents has connections to the school or to the peer group. The effective coordination of formal and informal support networks is not easy, however, because of the differences in background, values, goals, and definition of the problem that may provoke mutual distrust between formal and informal helpers. All too commonly, extended family members or neighbors reinforce a parent's skepticism of the potential helpfulness of a counselor or paraprofessional home visitor. Sometimes social workers undermine informal helpers by criticizing them or trying to assume their roles. But the integration of formal and informal helping is essential to promote the engagement of recipients in social support interventions and to provide a foundation for enduring assistance. Many well-meaning social support interventions fail because they do not sufficiently incorporate the natural helping networks of family members, resulting in assistance that is limited in time, scope, and impact.

Recipient Reactions to Assistance

Receiving assistance from another evokes surprisingly mixed reactions from most recipients. In addition to the feelings of pleasure and gratitude that helping naturally inspires, recipients may also experience various negative feelings (Fisher et al., 1982; Shumaker & Brownell, 1984). Receiving assistance can be humiliating and stigmatizing, especially when the need for assistance derives from inadequacies in the recipient (such as poor parenting, substance abuse, or inadequate personal or financial management) rather than from broader, impersonal circumstances (such as an economic recession or a natural disaster; Heller & Rook, 2001). Receiving help can also create feelings of failure, indebtedness, and inferiority, especially when assistance cannot be repaid, because of cultural norms of equity and reciprocity (Greenberg & Westcott, 1983). Moreover, if assistance cannot be reciprocated or compensated, the recipient may experience feelings of vulnerability or dependency because obtaining assistance from another violates norms of self-reliance and autonomy. There can also be sensitivity to privacy violations if helpers become intimately acquainted with aspects of the recipient's life that are not normally disclosed to others.

As a consequence of these reactions, recipients may rather paradoxically begin to resent the assistance they receive and the person providing it. This is especially likely when assistance is received from voluntary benefactors (whom one cannot reciprocate or otherwise compensate, enhancing the violation of equity and reciprocity norms) or strangers (with whom one does not share an ongoing rela-

tionship of mutual aid), and when the helper and the recipient are from similar backgrounds and circumstances (enhancing the inequity of the helping relationship). When recipients experience assistance as humiliating, demeaning, or intrusive, they are less likely to seek help in the future and are more likely to abridge or terminate a helping relationship if they are capable of doing so. This can explain why the recipients of assistance, to the surprise of their benefactors, may be ungrateful, fail to become engaged in the helping relationship, are often inexplicably absent from scheduled meetings, do not return phone calls, and progressively make the relationship unworkable or unsatisfying.

This analysis has surprising implications for providing social support to troubled individuals or families. It suggests that assistance is more easily accepted when recipients have opportunities to reciprocate or repay the aid they receive, perhaps in service to other individuals. It suggests that support is more readily received in circumstances that minimize the potential for humiliation or stigmatization, such as when support services are broadly available or universal (rather than specifically targeted to those in greatest need) and accessed in everyday settings (at home, for example, rather than at an agency office). This analysis suggests also that social support is more easily received when the recipient and the helper agree about the need for assistance and the reasons for the need. By contrast, assistance from another may be resented when the recipient perceives that it derives from unshared judgments of the recipient's inadequacy or incompetence. Provider efforts to preserve the dignity and the privacy of recipients are also important.

Other characteristics of the recipient can mediate the provision of social support. Because social support is given and received in relationships, many of the personal qualities necessary to creating and maintaining relationships are important also to the success of social support interventions (Cochran, 1990). When these capacities are deficient in troubled individuals owing to mental health or substance abuse problems, intellectual challenges, or the effects of stress itself, it can also complicate the receipt of social support (Heller & Swindle, 1983; Shinn et al., 1984). As earlier noted, for example, one portrayal of child neglect emphasizes the personal disorganization of neglectful parents, which becomes manifested as an inability to effectively organize home life, ensure children's physical well-being, and keep appointments with a help provider (Polansky et al., 1981; Seagull, 1987). These qualities, which are certainly not unique to child neglect, make it difficult for parents to create and maintain supportive helping relationships with other adults. For children and adults with emotional disorders, clinical symptomatology may

undermine the willingness or ability to maintain formal or informal supportive relationships. Stress can cause individuals to feel overwhelmed by life difficulties and to lack the time, energy, or hope to seek support from others. This can be especially true when families at risk live in dangerous neighborhoods that undermine access to neighbors, extended family members, and formal help providers (Eckenrode, 1983; Eckenrode & Wethington, 1990).

Because social support is not passively received, these recipient characteristics can pose formidable barriers to interventions based on supportive social relationships. Indeed, one of the most intractable obstacles to the success of social support interventions is the limited engagement and participation of recipient families. This suggests that a careful analysis of recipient reactions to assistance is necessary. When resistance to obtaining assistance derives from feelings of indebtedness, humiliation, or dependency, the conditions of support can be altered to reduce these perceptions and enhance participation in supportive relationships. This can occur by involving recipients in activities that help others, or that assist the intervention program, or that mobilize the recipient's special skills or capabilities. When supportive relationships are undermined by characteristics of the recipient, these problems must often also be addressed in the context of the intervention, such as in a substance abuse treatment or a social skills training program. This is not an easy task, however, because the personal characteristics of recipients that undermine their acceptance of help are often deeply rooted.

Cultural and Contextual Considerations

Among the most important personal characteristics of the providers and recipients of social support is their cultural and ethnic identity (Tietjen, 1989; Vaux, 1985). Cultural norms affect many of the central influences on giving and receiving social support and its psychological effects, including understandings of relationships, the nature of informal social networks, reciprocity and equity expectations in giving and receiving help, values concerning the relation between the individual and the group, attitudes toward assistance from formal helpers (such as therapists), and how help itself is evaluated (Dilworth-Anderson & Marshal, 1996; Jacobson, 1987). An appreciation of cultural and contextual factors related to social support is essential for understanding its associations with psychological well-being and developmental psychopathology. Cultural understanding is also critical to designing interventions in which social support is offered in a culturally aware manner to ensure that potentially beneficial inter-

vention strategies do not founder on delivery approaches that render them ineffective or even harmful.

A broad, well-known dimension by which concepts of the self in relation to others vary interculturally is that of individualism and collectivism (Triandis, 1989), or independence and interdependence (Markus & Kitayama, 1991). In cultures with an interdependent view of self, there is greater emphasis on connectedness with others and on deriving important features of identity and esteem from those associations; in cultures with a more independent view of self, there is a greater emphasis on the autonomy of personal thoughts and feelings, self-reliance, and privacy. These cultural views of the self are developed quite early and influence how children perceive themselves and their relationships from early childhood (e.g., Greenfield, Keller, Fuligni, & Maynard, 2003; Han, Leichtman, & Wang, 1998; Wang, 2004). By later childhood and adolescence, youth with backgrounds from interdependent cultures (such as Hispanic and Asian societies) acknowledge the expectation that they will assist and support family members more than do adolescents from European backgrounds (Fuligni & Pedersen, 2002; Fuligni, Tseng, & Lam, 1999). One study of Chinese American teenagers reported that such intergenerational expectations had neither positive nor negative consequences for psychological well-being (Fuligni, Yip, & Tseng, 2002). But the association between cultural values and social support is complex. A cultural emphasis on interdependence may facilitate help giving and help receiving through normative practices, but cultural values may make receiving help more difficult in many circumstances. One illustration is a study of older Japanese American adults living in New York City for whom norms of reciprocating support made receiving assistance difficult. Adults who held strong reciprocity norms and who received material support from their families were more depressed and were less satisfied with their lives than those who did not embrace strong reciprocity norms (Nemoto, 1998).

Cultural values and practices are related to a number of features of social networks and social support. Specifically, there is significant intercultural variability in the United States in (1) the nature and functioning of informal social networks, (2) the association between social support and psychological well-being, and (3) attitudes toward receiving assistance from formal helpers. Each of these sources of variability is relevant to designing culturally competent interventions involving social support and linking formal and informal sources of support to troubled children and their families.

Although the constituents of social networks are similar for families in different ethnic and cultural groups (e.g., in-

cluding immediate and extended family, friends, neighbors, and the like), the relative importance of each of these network members for social support is likely to vary. MacPhee, Fritz, and Miller-Heyl (1996) compared lower-income Native American, Hispanic, and European American parents living in the United States on their self-reported sources of support. They found that Native Americans reported more interconnected social systems, more frequent contact with extended kin (but not friends), more members who knew one another, and greater closeness with members of their support networks. Hispanic parents reported having the largest social networks, and, although these networks were close-knit, Hispanics were in general most likely to rely primarily on kinship networks for emotional support. Although they reported the lowest proportion of network members who could offer emotional support, they also reported the highest proportion of network members who could provide instrumental support (e.g., material assistance). European American parents had more diffuse social networks but also reported having a higher proportion of members available for instrumental support. Unlike parents in the other two groups, they reported that friends were the primary providers of emotional support rather than family members. Children also exhibit intercultural variability in the network members on whom they rely for support. In a study of fourth and sixth graders, DeRosier and Kupersmidt (1991) reported that children from Costa Rica rated their parents as the most important providers of support, and children in the United States rated their best friend as the most important source. These intercultural differences are important for understanding the network members who are likely to provide the most helpful forms of informal social support to children and families in need, as well as the avenues by which such support can be offered. It is a much different task to enlist the assistance of other family members in close-knit extended kinships than to call on the help of friends or other extrafamilial associates to provide social support.

Understanding cultural variability in social networks is especially important when children are the targets of social support interventions. For example, it is not necessarily wise to assume that parents are young children's primary sources of social support or that parents are gatekeepers to other sources of support, contrary to the tenor of research findings reviewed earlier. Instead, for families from cultural minorities, a child's earliest sources of support may arise within the extended family or in broader "fictive kin" networks, which are common for Hispanic and African American youth (e.g., J. E. Rhodes, Ebert, & Fischer, 1992; Sanchez & Reyes, 1999). In African American families, for

example, children and youth report receiving greater support from their extended families than do children from European families (Cauce, Felner, & Primavera, 1982; Dressler, 1985; Taylor, Casten, & Flickinger, 1993). Likewise, Hispanic values of familialism, involving strong feelings of support and reciprocity with family members, expand the social support networks of children to include adults beyond the immediate family unit (Sagobal, Marin, Otero-Sabogal, Van Oss Marin, & Perez-Stable, 1987). These conclusions are important not only for widening conceptions of the social networks of children and youth from culturally diverse families, but also for cautioning that problems in parent-child relationships, such as those arising from parental stress, substance abuse, or psychopathology, may not leave these children bereft of social support from other sources.

Likewise, parents may not act consistently as monitors, supervisors, and gatekeepers of children's access to other sources of social support. In recent immigrant families, for example, children and their parents may quickly differ in their familiarity with the environment, facility with the majority language, and access to social networks outside the family owing to different acculturation experiences at school and in the workplace. Although this may cause some parents to seek to restrict the access of children to extrafamilial social partners (Nanji, 1993), intergenerational differences in acculturative status mean that as children and youth become increasingly comfortable in the majority culture, parental restrictions are likely to become less effective and add stress to the parent-child relationship (Garcia Coll & Pachter, 2002). These influences may make it difficult for parents to function adequately as gatekeepers of children's access to extrafamilial sources of support.

Although social support comes from potentially diverse sources and is experienced in the context of cultural values, there is good evidence that social support contributes to psychological well-being for different cultural groups in the United States. Coatsworth and colleagues (2002) recently examined family, school, and friend support in relation to externalizing and internalizing behavior in Hispanic girls in middle school, and found that controlling for age, SES, and years in the United States, youth reports of greater perceived family support and teacher support (but not friend support) predicted fewer externalizing problems, and greater perceived family support and friend support (but not teacher support) predicted fewer internalizing problems. Support within the family was the strongest predictor of externalizing and internalizing symptomatology (Coatsworth et al., 2002). Likewise, in a short-term longitudinal study of African American male adolescents,

Zimmerman and colleagues (Zimmerman, Ramirez-Valles, Zapert, & Maton, 2000) found that although support from friends did not predict later outcomes, support from parents predicted diminished depression and anxiety. Rodriguez and colleagues examined perceptions of family and friend support in relation to stress and psychological adjustment in Hispanic college students (Rodriguez, Bingham Mira, Myers, Morris, & Cardoza, 2003). They found that higher support from family and friends predicted increased psychological well-being, although only friend support was a unique predictor of lower psychological distress.

However, cultural values may significantly mediate whether members of different ethnic and cultural minorities access formal—rather than informal—supports when facing psychological distress. This can occur for various reasons, including lack of awareness of formal services, distrust of providers (or providers who cannot speak their language), cultural beliefs that assistance from nonfamilial helpers is unnecessary or inappropriate, resistance to formal helpers from within the family or cultural group, or service delivery practices that are culturally uninformed. In the study of lower-income families described earlier, MacPhee and colleagues (1996) found that European American parents were significantly more likely to have sought professional therapy than were Native American or Hispanic parents, and they also tended more to seek professional help with parenting issues. Similar findings have been reported by Stevens (1988).

Findings such as these underscore the need for cultural awareness in designing interventions to enhance social support to children and families of culturally diverse groups. A culturally competent service delivery system will (1) identify groups that are underserved and seek to reduce cultural barriers that may interfere with service delivery by understanding their characteristics, resources, and needs; (2) orient program planning, staff training, and community involvement to ensure that the development, implementation, and evaluation of services are respectful of the values and practices of recipient families; (3) evaluate assessment and outcome procedures and instruments to ensure their appropriateness and validity for the children and families who are served; (4) build cross-cultural communication skills with program staff, including the appropriate use of interpreters and an ethnographic understanding of communication approaches within cultural groups; and (5) seek to develop an appreciation of cultural diversity as a facilitator rather than impediment to service delivery (Shonkoff & Phillips, 2000). These practices are especially important in services that seek to strengthen the benefits of social support interventions by linking formal support to informal support net-

works, especially in light of how “outside” helpers can be regarded with distrust or resentment by members of close-knit families or communities. In the end, cultural beliefs and practices are among the most significant personal characteristics mediating the needs of potential recipients and the providers of social support.

Clarity of Goals

Each of these contingencies in the efficacy of social support interventions underscores why clarity concerning the goals and purposes of intervention efforts is essential. Without clear goals, it is difficult to carefully design interventions that will accomplish specific goals for recipients that address their particular needs and living conditions and that result in measurable improvements (Gottlieb, 2000; Heller & Rook, 2001).

Achieving clarity in goals means answering a series of questions. First, in what ways do recipients lack social support that an intervention is expected to address? Answering this question requires a thoughtful understanding of potential recipients and their living circumstances and cultural background, including their personal needs and the resources as well as deficits that exist in their informal social networks and access to formal helpers. It is especially important to comprehend how stress is affecting potential recipients and their capacity to receive assistance from within or outside their natural social connections, and how shared stresses may affect the capacities of network associates to offer social support. Second, what are the specific goals that a social support intervention is meant to address? Multiple goals might be envisioned—providing emotional affirmation, offering instrumental or material aid, social support as a bridge to other forms of assistance, curbing inappropriate or dangerous conduct, preventing problematic behavior from occurring, promoting healing or developmental remediation, integrating formal with informal sources of support—but they should be related to the needs of recipients and identify outcome expectations that will enable an evaluation of the success of the effort. Third, who will offer support and how will they be identified, trained, and enabled to undertake this challenging task successfully? In what specific ways will they offer support, in what contexts, for how long and with what frequency and intensity, and in what social circumstances (e.g., working in teams or individually)? There are also trade-offs between the cost of an intervention and the training and professionalism of formal helpers, and the design of a social support intervention should approach these considerations thoughtfully, keeping in mind that volunteer helpers cannot

be expected to undertake the challenges or provide the long-term assistance that professional helpers may be better prepared to provide.

Taken together, questions such as these that focus on the needs of potential recipients, the capabilities of support providers, and the purposes of intervention help to ensure that efforts involving social support are well-designed to address the ways that social support can support psychological well-being for specific families and individuals in need, and that the resources of support providers will be equal to addressing these challenges. Moreover, addressing such questions also identifies the specific outcomes that the social support intervention is intended to affect, making it easier to conduct later evaluations of intervention effectiveness that are carefully tailored to the goals of the program.

Implications

Because the availability of social support will not in itself ensure benefits to recipients, considering the contingencies of social support is essential to planning interventions that will have greatest beneficial impact (see Thompson, 1995). In general, social support efforts are likely to be most effective in the following circumstances:

- The contributions of formal helpers are integrated and coordinated with the efforts of informal helpers in natural social networks and the latter are provided affirmative support for their efforts.
- There are clear, well-defined goals in mobilizing social support that are based on a careful analysis of the needs of target individuals or families and their social networks, the specific purposes for intervention, and the capabilities of support providers, and that identify outcome expectations that can constitute the basis for subsequent evaluation studies.
- Program planners understand how stress may impact the capacity of recipients to receive assistance and the functioning of informal networks of social support.
- Cultural beliefs and practices receive careful consideration and interventions are designed to respond sensitively to cultural diversity.
- Social support interventions provide bridges to broader community resources or other resources that can offer recipients long-term assistance.
- Help providers are supported through continuing supervision, training, and other forms of assistance, especially if they are volunteers or paraprofessional helpers.

- There are efforts to improve recipient reactions to accepting aid, which may include reducing feelings of vulnerability, failure, or inferiority by providing opportunities to reciprocate aid, promoting recipients' voluntary participation in efforts to help other individuals, and developing an environment of mutual respect.
- The need for social support is normalized in the community, so that receiving assistance is not stigmatizing or humiliating.
- Social support interventions are coordinated with other services that address other needs of troubled individuals or families or help recipients to function more successfully in socially supportive relationships (such as through social skills or substance abuse programs).
- When children are the targets of intervention, considerable attention is devoted to the needs of their parents and families in the context of potential two-generation interventions and the impact of family processes on the child's capacity to benefit from social support efforts.

Although these conclusions may seem straightforward and intuitively sensible, there are many reasons that intervention practitioners ignore them (Gottlieb, 2000). One reason is that owing to resource limitations, program philosophy, or tradition, most agencies or programs have only a limited range of support services to offer needy recipients and are thus constrained in their capacity to tailor services to specific client needs (Thompson & Flood, 2002). Another reason is that a detailed needs assessment takes time and, in the absence of validated, readily implemented assessment tools, this process may be abridged or ignored in the rush to provide services. Finally, because the budgets of most intervention efforts are limited, providing support to helpers assumes a lower priority than providing direct services to clients, even though this often results in high turnover and burnout among staff, especially when they are volunteers or paraprofessionals. On the other hand, the same resource limitations make investment in well-trained or formal helpers an impossibility.

Nevertheless, the importance of these contingencies to program success is reflected in the costs of ignoring them when potentially helpful intervention approaches encounter difficulty. One illustration is home visitation. During the past several decades, home visitation has become the most enthusiastically supported and widely recognized approach to providing social support for needy families. The fundamental strategy uniting diverse home visitation programs is the delivery of information, guidance, and emotional support to family members in their homes, often in the context

of two-generation efforts in which improving the well-being of the child is the basic goal. Doing so provides an avenue for offering diverse forms of social support, overcomes some of the barriers these families otherwise face when obtaining needed assistance (such as lack of transportation or health insurance) and establishes a relationship of trust with a home visitor who can provide individualized assistance and bridge connections to broader resources (Thompson, 1995; Wasik & Bryant, 2000). Home visitation has provided the foundation for a number of intervention efforts throughout the country, most notably the Healthy Families initiative, developed by the National Committee to Prevent Child Abuse, which has established a nationwide consortium of hundreds of home visitation programs throughout the country serving families at risk (Daro, 2000; Daro & Harding, 1999). A large number of home visitation programs are funded by direct legislative appropriation in many states, or by project grants from federal agencies, as central features of statewide efforts to strengthen child health and development, prevent child maltreatment, and improve parent-child relationships.

There have been a number of reviews and evaluations of home visitation initiatives (see, e.g., General Accounting Office [GAO], 1990; Olds & Kitzman, 1993), but the most recent and large-scale evaluation efforts have yielded the most startling conclusions. Based on sophisticated evaluation studies of six of the most well-known home visitation models that have been implemented nationally, Gomby, Culross, and Behrman (1999) concluded that program benefits were modest and inconsistent across program sites, benefits were enjoyed by only a subset of the families who participated in the program, and programs failed to accomplish most, if not all, of the goals of the home visitation effort. The recent results of a meta-analysis of 60 home visitation programs provided evidence that families in home visitation programs benefit from their participation, but these effects are modest and studies do not offer insight into what kinds of home visitation initiatives benefit what kind of participants. These reviewers concluded that "the utility of home visiting programs cannot be clearly stated" (Sweet & Appelbaum, 2004, p. 1448), and Gomby and colleagues recommended

that any new expansion of home visiting programs be reassessed in light of the findings . . . [and] that existing programs focus on program improvement, that practitioners and policymakers recognize the inherent limitations in home visiting programs and embrace more modest expectations for their success, and that home visiting services are best funded as part of a broad set of services for families and young children. (p. 6)

Several problems of program implementation were identified by these reviewers and by other evaluations of family support programs emphasizing social support (e.g., Halpern, 2000; Larner, Halpern, & Harkavy, 1992) as helping to account for these discouraging conclusions. They include the inconsistent participation of recipients, the importance of supporting help providers, the need to develop community connections, and the problem of lack of clarity in program goals and expectations.

The failure to fully engage families in the program and the high attrition rates of participants have been identified as significant challenges for virtually all home visitation programs. According to Gomby and colleagues (1999), between 10% and 25% of families invited to participate in home visitation programs decline, and between 20% and 67% of the families who enroll fail to complete the program. Moreover, even when families enroll and remain in home visitation programs, they tend to receive only about half or fewer of the planned number of contacts with the home visitor. The reasons for problems in participant engagement are unclear but are likely related to residential relocation, busy or disorganized family schedules, and other typical characteristics of recipients. But lack of engagement may also be related to the mixed recipient reactions to obtaining assistance discussed earlier, especially if family members do not perceive that home visitation addresses their needs and concerns, or feel embarrassed, indebted, or vulnerable because of the services they receive (Margie & Phillips, 1999).

A second problem in successfully implementing home visitation programs is the lack of training, supervision, and support for home visitors, which contributes to the high turnover rates that are observed in most home visitation programs (GAO, 1990; Gomby et al., 1999). It is common for home visitors to report shorter visits than planned, broken appointments that are not rescheduled, and becoming preoccupied with immediate family crises rather than the delivery of intended education or guidance during home visits. Home visitors are further challenged when working with culturally or linguistically diverse families, at-risk populations, or parents who suffer from depression, domestic violence, or substance abuse (Margie & Phillips, 1999). Moreover, several studies have found that how the intended curriculum of a home visitation intervention is implemented varies significantly depending on the values and orientation of the home visitor (Baker, Piotrkowski, & Brooks-Gunn, 1999; Wagner & Clayton, 1999). At times, in other words, what actually occurs during home visitation may be much different from what program designers had intended. Furthermore, the high turnover of home visitors

undermines the relationship between participants and the program, and this may be one contributor to the lack of family engagement. Turnover can be especially difficult for adults in the highest-risk families, who may have fewer alternative sources of support on which to rely and who often have histories of abandonment and relational dysfunction. These challenges to program implementation are directly related to the training, supervision, and support provided to home visitors, especially those who are volunteers or paraprofessionals. However, personnel, training, and supervision account for most of the costs of a home visitation program, and thus poorly or inconsistently funded programs are likely to scrimp on these essential features of service delivery.

Another challenge to effective program implementation is the failure of many home visitation programs to explicitly establish the development of community supports as a central goal for recipient families. This is unfortunate because, by contrast with the traditional social work model, the social support approach incorporated into home visitation recognizes that a home visitor cannot provide all that recipients need, and consequently one of the significant goals of intervention must be to help families forge associations within their communities to individuals and agencies that can offer longer-term support. Moreover, community connections and visibility can also enhance the positive regard for a home visitation program in the neighborhood, and this can contribute to improving family engagement and strengthening the connections between family members and community services.

Finally, the reviews by Gomby and colleagues (1999) and Sweet and Appelbaum (2004) each identified program goals as problematic because they were unclear, unduly ambitious, and/or were not carefully translated into intervention strategies. Gomby and colleagues emphasized, in particular, a renewed appreciation that home visitation programs must have modest expectations for what social support alone can accomplish for needy families. They suggest that home visitation efforts be combined with other services that can address other family needs. This is an additional reason for consolidating stronger connections between family members and community resources so that home visitors do not seek to do it all. Home visitation programs that focus on limited, clear, well-defined, and realistic objectives have the greatest chance of success by enabling program staff to sustain program focus and to use limited resources to achieve realistic expectations (GAO, 1990).

These concerns with the effective implementation of home visitation programs are familiar in light of the foregoing analysis of the contingencies of social support inter-

ventions. They do not indicate that efforts to improve social support in the lives of troubled children and their families are inappropriate or worthless. They do, however, suggest that it is crucial to move beyond a general expectation that providing social support in itself will yield many benefits to recipients. Programs must recognize that (1) social support is multifaceted; (2) potential recipients have diverse needs, expectations, and personal and cultural backgrounds; (3) their natural social networks have unique resources and difficulties; (4) their communities likewise have unique constellations of material and human capital; (5) support providers have needs for training and support that are central to an effective intervention; and (6) social support alone cannot address the complex needs of recipients. The importance of clear thinking concerning the purposes of social support interventions, how these objectives should be translated into program strategies, and how the outcomes of these efforts should be evaluated is warranted.

CONCLUSIONS AND FUTURE DIRECTIONS

One of the central conclusions from the research on social support and developmental psychopathology is how complicated the provision of social support in everyday circumstances is, yet how beneficial it is for psychological functioning. When people are surrounded by natural networks of family, friends, neighbors, coworkers, and others who offer emotional guidance and instrumental aid and monitor well-being, the odds in favor of psychological health and healing are meaningfully improved. However, another central conclusion of this research is how difficult it is to create the benefits of natural forms of social support in preventive or therapeutic interventions. This not only owes to the challenges of instituting formal helping relationships that can offer social support, but also because when natural social networks are not functioning supportively (because they are drained or stressed, for example), it is difficult to reconstitute them in healthy and helpful ways. Added to these challenges is the neediness of support recipients and how their personal and ecological characteristics can pose obstacles to the success of social support interventions. In short, the benefits of social support are easy to envision but difficult to implement. This poses a fundamental challenge for researchers, theorists, clinicians, and practitioners who, after the initial wave of enthusiasm for the preventive and therapeutic benefits of social support interventions 2 decades ago, must now confront the host of practical challenges to effectively implement social support in the lives of needy families. As the evaluation studies of home visitation

interventions illustrate, however, there is cause for hope. From the varieties of programs that have documented measurable and predictable benefits for recipients—and from those that have failed to do so—there is now a wealth of good ideas for crafting more carefully conceived, thoughtfully designed social support interventions that have greater promise of success. It remains to be seen if the enthusiasm for the psychological benefits of social support interventions can be sustained in the current environment of conceptual rethinking, more careful and modest goal setting and, as always, limited budgets.

There are many ways an examination of social support and developmental psychopathology illustrates the principles of a developmental psychopathology perspective (Cicchetti & Cohen, 1995). Most fundamentally, there appears to be considerable consistency in the processes and outcomes of social support in diverse developing populations, both those that face atypical challenges and clinical difficulties and those that do not. Although at-risk children and families encounter unique problems in obtaining or receiving social support, and particular forms of support may be especially important to different recipient populations, the potential benefits of well-designed social support interventions are consistently clear in our review of diverse clinical and developmental literatures. The continuity in developmental processes between atypically and typically developing populations is, of course, a hallmark of the developmental psychopathology view and appears to be supported by the benefits that well-crafted social support interventions can offer needy individuals of all kinds. However, our review of research on social networks has shown that contrary to the simplified views of social support of several decades ago, there are both risk factors as well as protective factors in the everyday social relationships from which informal social support is constituted. Especially for troubled families and children, these relationships may be sources of stress and difficulty in neighborhoods that may be dangerous or deprived, and thus simply enrolling individuals into broader social networks will not ensure access to social support. Instead, thoughtfully designed social support interventions must carefully determine the resources as well as the liabilities that exist in natural social networks in order to evaluate whether these networks can be strengthened to increase support to target individuals, or whether new sources of social support must be identified. The need to consider both risk factors and protective factors as contributors to psychological health or dysfunction is an important feature of a developmental psychopathology analysis, as is the concept of multifinality, which is also illustrated in the social support research. Multifinality suggests that any component of a developmental system may function differently depending on the organization of the system in which it oper-

ates. In our review, we have indicated many instances in which social support can have benefits but also create liabilities for well-being depending on the form of social support and other features of the social ecology of the child and family. These include situations in which individuals offer emotional support but, in doing so, condone or excuse psychologically unhealthy practices (such as child maltreatment or pathological forms of child anxiety) and circumstances in which social support is offered at a price (of engaging in relationships that also cause stress) that significantly alters its benefits for the recipient. This affirms the conclusion that social support is not in itself a panacea, but its benefits avail only when it is thoughtfully incorporated into the lives of its recipients.

The research literature on social support is broad and expansive, yet there remain significant gaps in knowledge that future research must address, especially with respect to issues of developmental psychopathology. First, there is a critical need for better understanding of the social support *process*, especially when children and families are concerned. What are the specific ways that social support is given, experienced, and received in the everyday social relationships from which it is derived? What specific things do network associates do to make recipients feel supported? How is the process of social support experienced differently by young children, older children, and adolescents in relation to their relative understanding of the complexity of relationships and their own social support needs? In what ways is the experience of social support significantly altered by clinical psychopathology, whether children or parents are depressed, abusive (or abused), or troubled in other ways? In a similar fashion to an earlier generation of studies of the clinical process that helped to identify some of the important features of the therapeutic process related to clinical outcomes, understanding of social support would benefit from finer-grained investigations that examine the process of social support as it is experienced by helper and recipient (Barker & Pistrang, 2002). Such studies, which should include field studies as well as experimental probes, could meaningfully inform the design of social support interventions by promoting more effective intervention design and enabling better training of social support providers.

A related, and significant, concern for future research concerns determinants of the *perception* of social support. As we have noted, an individual's perception that social support is available and accessible is the most important dimension of social support predictive of psychological well-being, but it is not directly and strongly linked to enacted support (see also Hogan et al., 2002). This raises new questions concerning the other determinants of perceptions of social sup-

port and, more broadly, how individuals make judgments of social support. Lakey and his colleagues (e.g., Lakey & Lutz, 1996; G. L. Rhodes & Lakey, 1999) have argued that perceptions of social support derive from (1) personality characteristics of the recipient (e.g., a secure or insecure attachment history, interpretive biases, extraversion), (2) characteristics of the helper (e.g., personality factors such as empathy, enacted support), and, most important, (3) the interaction between helper and recipient (e.g., their similarity in background and outlook). This is a heuristically powerful analysis and invites both broader inquiry into the determinants of perceptions of social support and a thoroughgoing developmental analysis of these determinants (e.g., How do developmental changes in support needs, understanding of relationships, and other factors contribute to changing perceptions of social support with increasing age?). One important implication of research on this topic concerns intervention. If perceptions of social support are central to the preventive and therapeutic benefits of social support, then perhaps support interventions could be effectively oriented toward changing perceptions of social support in the minds of needy recipients. If needy individuals begin to perceive their existing social networks as offering greater opportunities for social support, is their own sense of well-being enhanced (even if there have been no significant changes in the behavior of network associates) and, more important, do they become more willing and capable of fostering social support on their own?

We also urge greater, and more systematic, examination of the nature and efficacy of interventions incorporating social support. As Barrera and Prellow (2000) have noted, there is very little research examining whether changes in social support are directly linked to changes in psychological well-being, despite a wealth of suggestive research findings. Moreover, there is relatively little inquiry into the long-term effects of social support interventions: Most evaluation studies examine immediate or short-term outcomes with little inquiry into enduring influences. Furthermore, much remains to be learned about the recipients of social support and, in particular, what kinds of families and children are likely to benefit most from social support interventions, and for whom such efforts are likely to prove ineffective. As the work of Polansky and his colleagues (1981) on neglectful families exemplifies, the research reviewed in this chapter shows that potential recipients differ significantly in their capacity to receive social support and to benefit from it, and further inquiry into individual and developmental differences will inform intervention design.

There is also considerable need for further study of developmental considerations related to giving and receiving so-

cial support within families. The intersection of the social networks of parents and offspring offers a start to understanding the direct and indirect avenues by which parents' experience of social support influences offspring, and the roles of parents as gatekeepers to children's access to social networks outside the home affirms the importance of two-generational thinking in providing social support to children. Beyond these, however, developmental inquiry into how children's social networks change with age, the manner in which these networks become increasingly self-regulated and independently accessed, how children's perceptions of social support and capacities to access support from others change with age, and related issues would contribute to a more fully developed understanding of social support in its normative and clinical dimensions.

Beyond these, there are a number of basic questions that continue to merit attention:

- How do natural networks of social support function in everyday life? How is their functioning affected by aspects of neighborhood and community life that may inhibit or encourage contact with others. How are they affected by cultural values?
- How do individuals experience support from informal and formal helpers in everyday life? How do they identify particular persons as sources of reliable assistance, and what are the characteristics of these people?
- How do stress, family turmoil, and the psychological problems of a family member affect social support processes within families? What causes some families to seek and gratefully accept assistance and other families to become withdrawn and isolated? What are the characteristics of potential help providers that may affect how families respond to offered aid?

Although inquiry into social support and its psychological benefits has been ongoing for several decades, this essential component of preventive and therapeutic success is current and vital. For children in psychological turmoil and families in distress, the work of developmental psychopathologists on social support remains essential.

GENERAL CONCLUSION	73
REFERENCES	74

By tradition, students of socialization have directed their primary energies toward understanding processes whereby parents' child-rearing strategies and behaviors shape and influence their offspring's development. It was possible 15 or so years ago, then, for Belsky and Vondra (1988, p. 153) to observe, on reviewing the literature on the determinants of parenting, that "whereas great effort has been expended studying the characteristics and consequences of parenting, much less attention has been devoted to studying why parents parent the way they do." Even though it remains the case that research on the sequelae of parenting outpaces that on the determinants of mothering and fathering, a great deal has changed over the past decade and a half with respect to empirical inquiry into "why parents parent the way they do." In large measure, this change was stimulated by Bronfenbrenner's (1979, 1986) writings on the ecology of human development, which did much to highlight the contextual embeddedness of child development. To under-

stand the development of children, Bronfenbrenner (1979) asserted, one needed to focus not only on the immediate environments—family, day care, and school—in which children spend so much of their waking day, but on the neighborhood, community, and broader societal context in which the child and family are embedded, including the workplace in which parents spend much of their time and the social supports available to them.

If one reflects on the empirical progress that has been made over the past 15 years, to say nothing about changes that have taken place in the way scholars conceptualize the determinants of parenting, then it becomes apparent very quickly that much has changed over the past half-century in thinking about the origins of individual differences in parenting. Such change is perhaps no better illustrated than by considering changing models of the etiology of child abuse and neglect. Child maltreatment, after all, can be regarded as a case of parenting gone awry or dysfunctional parent-

ing, so it serves as a window through which to view changing notions of why parents parent the way they do. We begin this chapter, therefore, by outlining changing models of the causes of child abuse and, in so doing, underscore one of the core themes of developmental psychopathology, namely, the interrelation of normality and pathology (Cicchetti, 1984; Cicchetti & Cohen, 1995; Sroufe & Rutter, 1984). That is, by focusing on parental dysfunction, we presume that an understanding of its determinants can illuminate forces fostering more competent and growth-promoting parenting (Belsky & Vondra, 1988).

After considering changing conceptions of the causes of child maltreatment, we outline a model of the determinants of parenting that Belsky (1984) advanced almost 2 decades ago but that still serves to guide much research (e.g., van Bakel & Riksen-Walraven, 2002). Belsky's model will serve as the overarching framework guiding the review in the remainder of this chapter of relevant research that has (mostly) emerged since the model's original formulation. To further underscore the view that studies of the abnormal can illuminate understanding of the normal, and vice versa, the review focuses on work concerned with development and parenting within the normal range, as well as with psychopathology and disturbances in parenting.

Before proceeding to consider changing views of the etiology of child abuse and neglect and reviewing, using Belsky's (1984) conceptual framework, research on the determinants of parenting, it is necessary to consider an issue barely on the screen 2 decades ago, namely, the heritability of parenting. Such a focus is essential because virtually all of the evidence reviewed in the main body of this chapter fails to take into account the possibility that many findings presumed—and even interpreted (for heuristic purposes) in this chapter—to reflect environmental influences on parenting may actually be a function, at least in part, of genetic inheritance. It would be a serious error not to caution the reader about this severe limitation of most relevant research to ensure that all conclusions to be drawn in this chapter are tempered by appreciation of this core limit in the design and interpretation of so much research.

A CAUTION: THE HERITABILITY OF PARENTING

In addition to witnessing an outpouring of research on the determinants of parenting, the past 15 years have also witnessed an outpouring of research on the heritability of behavioral development. Included in this ever-expanding body

of work has been research on parenting and the home environments that parents provide their offspring (McGuire, 2003). Much of this work has been viewed by those who conducted it as an antidote or corrective to that produced by many scholars interested in how parenting shapes psychological and behavioral development who do not entertain the possibility, or at least who do not design their research in light of the possibility, that the reason so much evidence connects parenting and child functioning is because genes passed on to children may shape both the parent's parenting and the child's development. Thus, associations linking parenting and child development may not document not environmental influences (i.e., parenting) on psychological and behavioral development, as so often presumed, but the influence on parents and their children of genes they share.

Several studies report genetic influence on individual differences in parenting (measured via self-report questionnaires; Plomin & Bergman, 1991; Spinath & O'Connor, 2003). In one, relying on retrospective child-rearing environments of adult twins who were reared apart, Hur and Bouchard (1995) found that genetic factors accounted for 44% of the variance in perceptions of support in the childhood family environment. In another study, of more than 700 sibling pairs 10 to 18 years of age, including identical or monozygotic (MZ) twins (sharing 100% genetic material), fraternal or dizygotic (DZ) twins (sharing 50%), full sibs (sharing 50%), half-sibs (sharing 25%), and stepsiblings (sharing 0%), Plomin, Reiss, Hetherington, and Howe (1994) documented significant genetic effects for 15 of 18 composite measures of the family environment (reported by parents and children), with average heritabilities of .27. More recently, Spinath and O'Connor reported genetic effects ranging from not different from zero (i.e., rejecting) to .73 (i.e., overprotective) in a sample of 300 German twin pairs who reported on their own parenting behavior. Clearly, when one looks across many related studies, findings are not entirely consistent (O'Connor, 2002), even when the same measure is used (Kendler, 1996; Losoya, Callor, Rowe, & Goldsmith, 1997; Perusse, Neale, Heath, & Eaves, 1994).

The first study to examine the heritability of parenting and the home environment was reported by Rowe (1981, 1983). Using the classical twin design, Rowe (1981) examined adolescent twins' ratings of parental warmth and control, finding that MZ twin pairs, who share 100% of their genes, were significantly more alike in how they perceived parental warmth than DZ twins, who share only 50% of their genes (like any two full siblings), indicating genetic influence, a finding that did not materialize with respect

to parental control. Similar results emerged in Rowe's (1983) second study that focused on adolescent twins and nontwin siblings, with similarity in nontwin siblings being comparable to that of DZ twins and substantially less than that of MZ twins.

These early findings pertaining to the differential heritability of warmth and control dimensions of parenting were confirmed in a study of older Swedish twins who were asked about their family environment half a century earlier (Plomin, Pedersen, McClearn, Nesselroade, & Bergman, 1988) and in a study by Kendler (1996) of adult twins reporting on how they parented their (own) twins and their twin offspring reporting how they were parented. Plomin et al.'s (1994) aforementioned inquiry also found that parental control, as indexed by a parent report composite measure of monitoring, had the lowest heritability estimate of all 18 composites examined. Losoya and associates (1997), too, found greater evidence of heritability in the case of positive support/warmth (e.g., warm, encourage independence) than negative control (e.g., strictness, aggravation) in their investigation of the similarity of adult twins who were parents. In subsequent work, Perusse et al. (1994) studied a large sample of older twins who also reported on their previously experienced parenting practices; as in other studies, modest genetic effects emerged for the rearing dimensions of care and overprotection (i.e., warmth).

It is not always the case, however, that differential heritability for parental warmth and control emerge in genetically informed studies, as Baker and Daniels (1990) found significant genetic effects for both dimensions of parenting in a study of adult twins. Relatedly, Plomin, McClearn, Pedersen, Nesselroade, and Bergman (1989) detected significant heritability with respect to control in their investigation of the family environment of MZ and DZ twins who had been reared together or apart.

Evidence for genetic contribution to measures of parenting and the family environment is not limited to questionnaire assessments. Genetic effects have been found, for example, in sibling adoption studies comparing nonadoptive and adoptive siblings for videotape observations of mother-infant interaction (Dunn & Plomin, 1990) and mother-child-sibling interactions (Rende, Slomkowski, Stocker, Fulker, & Plomin, 1992). Genetic effects have also emerged in analyses of the widely used observation-interview instrument, Home Observation for Measurement of the Environment, also known as the HOME (Braungart, Plomin, & Fulker, 1992).

In sum, then, the reader should be cognizant of the fact that much of the correlational evidence to be considered linking various developmental and contextual factors with

parenting may reflect the impact of shared genes as much as true environmental influences.

HISTORICAL PERSPECTIVES: THE ETIOLOGY OF CHILD MALTREATMENT

By tradition, three general perspectives have been employed to account for the etiology of child maltreatment; these can be referred to as the psychiatric or psychological model, the sociological model, and the effect-of-the-child-on-the-caregiver model (Belsky, 1978; Parke & Collmer, 1975). By far, the account of child maltreatment most widely subscribed to by the lay public, at least traditionally, falls within the psychiatric model, which focuses exclusive attention on the individual maltreating parent. Essentially, the psychiatric model emphasizes the role that the parent plays, because it is the parent who is the direct perpetrator of mistreatment. Perhaps the most compelling evidence that implicated psychological factors in the etiology of child mistreatment, and thereby focused attention on the psychiatric/psychological makeup of the individual abuser, derived from reports linking parents' own (problematic) child-rearing histories with their subsequent (abusive) parenting (e.g., Altemeier, O'Connor, Vietze, Sandler, & Sherrod, 1982; Spinetta & Rigler, 1972).

Those whose view of the causes of child maltreatment emphasized the rearing histories and psychological character of abusive or neglectful parents were following a tradition established by students of Freud, who were among the first to formally advance ideas about why parents parent the way they do. These ideas grew out of their interest in the nature and structure of personality and the ways development could go astray in early childhood and result in psychopathology. Drawing from clinical experience, a central tenet of many of these theories was that the parent's personality determined the nature of parenting and the parent-child relationship and, in turn, child development. Attention was focused largely on pathological aspects of parental character and the ways these factors gave rise to child psychopathology. Anna Freud (1955/1970), for example, discussed mothers who rejected their children, sometimes due to psychosis but more often because of neurotic conflicts. She wrote, "The [mother's] behavior toward the child is understood best when viewed in terms of her own [intrapsychic] conflicts" (p. 382). Spitz (1970, p. 504), too, wrote about maternal rejection as well as permissive and hostile parenting behavior, arguing that "the mother's personality acts as the disease-provoking agent" in the parent-child relationship. Winnicott (1948/1975, p. 93) also emphasized problematic aspects of the parent's personal-

ity, asserting that "the child lives within the circle of the parent's personality and . . . this circle has pathological features." As Holden and Buck (2002) recently noted, the common theme among these psychoanalytic theorists was that if parents' emotional needs had not been met during the course of their own development, then these unresolved needs would be reflected in their (compromised) parenting behavior. Conversely, it was assumed that if parents had adaptive and flexible personalities, derived from emotionally supportive child-rearing histories, they would behave toward their children in growth-promoting ways.

A radical critique of the psychiatric model of child maltreatment was advanced by sociologists who contended that psychologists and psychiatrists placed too much—meaning virtually exclusive—emphasis on the attributes of the maltreating parents, failing to acknowledge the stressful conditions in which they lived (and parented) and, in consequence, essentially "blaming the victim" (Belsky, 1978). The psychiatric model, according to these sociological critics, failed to recognize and grant importance to the social conditions that create stresses that undermine family functioning, as well as the cultural values and practices that encourage societal violence in general and the corporal punishment of children in particular (Gelles, 1973, 1975; Gil, 1971; Light, 1973). Some of the most compelling evidence in support of this model derived from studies linking unemployment, labor market shrinkage, and social isolation with child abuse and/or neglect (Garbarino, 1976, 1977a; Gelles, 1975; Light, 1973).

According to sociological critics of the psychiatric model of child maltreatment, parents must be considered victims of these social forces. The basic premise of the sociological model of child abuse was that important societal characteristics foster child maltreatment. These include high levels of violence and its frequent usage as a strategy for settling human relations disputes, conceptions of children as the property of their parents, and the widespread embrace of such beliefs as "Spare the rod and spoil the child." Under such societal and cultural conditions, the fact that parent-child conflict eventuates in child abuse, especially when parents confront contextual stressors such as unemployment, social isolation, and marital distress, should not be surprising, according to the sociological model. In essence, the social and cultural soil is regarded as fertile when it comes to fostering the mistreatment of children.

Implicit in both the psychiatric and sociological models of child maltreatment was the assumption that parent-child relations are unidirectional, with only parents exercising influence in this subsystem of family relations. The effect-of-the-caregiver model challenged this basic assumption

and underscored the role that the child's own health and behavior played in determining the course of parent-child relations (Parke & Collmer, 1975). Evidence to suggest that children might be responsible for, or at least contribute to, the mistreatment they experience came from evidence indicating that one child within a family was often singled out for mistreatment (Kadushin & Martin, 1981). Also consistent with a child-effects point of view was evidence that prematurity and low birthweight characterized the perinatal histories of a disproportionate number of abused children (Fontana, 1971; Klein & Stern, 1971; Martin, Conway, Beezley, & Kempe, 1974) and that mistreated children exhibited deviations in social interactions and general functioning prior to their reported abuse (Starr, Dietrich, Fischhoff, Ceresnie, & Zweier, 1984).

Certainly by the mid-1970s, if not before, it had become apparent that a model narrow in scope, whether emphasizing the personality and developmental history of maltreating parents, the social stresses that abusive families experience and the social context in which they function, or the role that children play in eliciting their own mistreatment, must inevitably fail in its attempt to account for the multifaceted processes at work in child abuse (Parke & Collmer, 1975). In response to the widely recognized need to integrate these distinct approaches to the etiology of child maltreatment, Belsky (1980) offered an ecological synthesis of these clearly complementary approaches, using a modified version of Bronfenbrenner's (1979) ecological framework. More specifically, Belsky observed that

while abusing parents enter the microsystem of the family with developmental histories that may predispose them to treat children in an abusive or neglectful manner (ontogenic development), stress-promoting forces both within the immediate family (the microsystem) and beyond it (the exosystem) increase the likelihood that parent-child conflict will occur. The fact that a parent's response to such conflict and stress takes the form of child maltreatment is seen to be a consequence of both the parent's own experience as a child (ontogenic development) and of the values and child-rearing practices that characterize the society or subculture in which the individual, family, and community are embedded (the macrosystem). (p. 33)

BELSKY'S (1984) SOCIAL-CONTEXTUAL MODEL OF THE DETERMINANTS OF PARENTING

When considered in their entirety, available theory and research on the etiology of child abuse and neglect drew attention to three general sources of influence on parental

functioning: (1) the parents' ontogenic origins and personal psychological resources (psychiatric model/ontogenetic development), (2) the child's characteristics of individuality (effect-of-child-on-caregiver model/microsystem), and (3) contextual sources of stress and support (sociological model/exo- and macrosystems). Using this foundation, Belsky (1984) advanced, as part of a special issue of the journal *Child Development* focused on integrating the study of development and psychopathology (Cicchetti, 1984), a process model of the determinants of parenting to explain why parents perform well and poorly in the parental role, recognizing that insights into parenting in the normal range could derive from research and thinking about seriously problematic parenting (i.e., abuse and neglect). Belsky argued that parenting is directly influenced by forces emanating from within the individual parent (personality), from within the individual child (child characteristics), and from the broader social context in which the parent-child relationship is embedded, specifically, marital/partner relations, social networks, and occupational experiences of parents. Further, his process model presumed that parents' developmental histories, marital relations, social networks, and occupational experiences influenced their individual personalities and general psychological well-being and, thereby, parental functioning and, in turn, child development. He further theorized that the parent's psychological makeup, shaped in part by his or her developmental history, influenced marital relations, social network functioning, and experiences at work. As such, Belsky's model was based on the notion (1) that parenting is multiply determined, (2) but that characteristics of the parent, the child, and the social context are not equally influential in supporting or undermining growth-promoting parenting because (3) personality shapes parenting indirectly by first influencing the broader context in which parent-child relations exist (i.e., marital relations, social networks, occupational experiences), as well as directly.

Belsky's (1984) model of the determinants of parenting had much in common with thinking by Cicchetti (Cicchetti & Lynch, 1993; Cicchetti & Rizley, 1981; Cicchetti & Toth, 1998) about the etiology of child maltreatment. Both theoreticians assumed parenting to be determined by the relative balance of potentiating (i.e., risk) factors and compensating (i.e., protective) factors experienced by a given family. Problematic parenting, whether it took the form of child maltreatment or just harsh or inconsistent or neglectful or permissive parenting, was presumed to occur when risk factors, be they transient or enduring, outweighed any compensatory influences. Central to conceptual frame-

works offered by both thinkers was the recognition of the multiple pathways by which individual (parental personality attributes or child characteristics), historical (parental developmental history), and social (marital quality, social support, occupational stress) factors and processes combine to shape parental functioning. These were not frameworks exclusively or even disproportionately emphasizing "main effects," then, as abusive or neglectful parenting—as well as competent, growth-promoting parenting—were regarded as resulting from the interaction between parental stresses and supports. At the same time, and as already noted, in Belsky's model in particular, all putative forces of influence were not regarded as equally powerful. Characteristics of parents themselves were considered of primary importance because they not only directly influenced parenting, but shaped the other forces also theorized to impact parenting. It is for this reason that attributes of parents are given disproportionate attention in this chapter, by including separate sections on parent's developmental history, parental psychopathology, and parental personality.

Having briefly reviewed the foundations of Belsky's (1984) model of the determinants of parenting in prior thinking about the etiology of child maltreatment, we turn now to examine research on the multiple determinants of parenting, beginning first with child characteristics, before moving on to consider characteristics of the parent and the social context. Given the tremendous growth of research in this general area of inquiry over the past 2 decades, we have decided not to cover all the domains of influence in Belsky's original model, choosing to emphasize those most directly reflective of the parent (developmental history, psychopathology, personality), the child, and the immediate family (i.e., the marriage). We thus do not address two other dimensions of Belsky's original model, namely, social support and occupational experiences. Instead, we examine a "forcefield" that was not even on the developmental horizon in 1984, but has come to be regarded as an important context of development beyond the immediate family and that shapes parenting, namely, the neighborhood, before drawing some general conclusions.

CHILD CHARACTERISTICS

Even though the child's role in shaping the parenting he or she receives has not always been appreciated, few students of parent-child relationships today fail to acknowledge the reciprocal nature of the relationship (Bell, 1968). Rothbart

(1989, p. 27) observed, for example, that “the infant’s temperament regulates and is regulated by the actions of others from the earliest hours.” This, of course, is a far cry from the perspective of social learning and psychoanalytic approaches to the study of parenting, which accorded the child a minor role in shaping the care received from parents. Temperament is the characteristic of children that has been examined most intensively in research on the determinants of parenting; it will thus be the exclusive focus of this section of the chapter.

Defining Temperament

Thomas, Chess, Birch, Hertzog, and Korn (1963) were perhaps the first to emphasize the role of individual differences in children when it came to understanding the ways parents treat their children. Intensive study of a small sample of middle-class Jewish families led them to propose a set of nine infant temperament categories (activity level, rhythmicity, approach versus withdrawal, adaptability, intensity, threshold, mood, distractibility, and attention span) and identify types of infants, specifically “difficult” and “easy,” based on the challenges they pose for their parents in taking care of them. Difficult infants scored high on negative mood and withdrawal, low in adaptability, high on intensity, and low on rhythmicity. Easy infants scored in reverse fashion on these select dimensions of temperament. Thomas et al. also emphasized the goodness of fit between characteristics of children and of parents when it came to understanding how parents responded to children’s temperaments and the relation between temperament and future child functioning.

Although the notion of infant difficulty continues to influence the thinking of many developmentalists and clinicians, it remains the case that efforts to cluster children empirically based on Thomas et al.’s (1963) definition of difficultness have not met with great success (Bates, 1989). Moreover, extensive factor-analytic research on parent report measures of temperament indicates that fewer than the nine dimensions can be used to capture much of the individual variability in child behavior for purposes of studying parent-child relations (and many other topics; Rothbart & Mauro, 1990). Putnam, Sanson, and Rothbart (2002) draw attention to the following dimensions in infancy: fear, irritability/anger, positive affect, activity level, attentional persistence, and rhythmicity.

These same scholars highlight an emerging consensus with respect to temperament factors relevant for 3- to 8-year-old children, pointing to three broad dimensions (see

also Rothbart, Ahadi, Hershey, & Fisher, 2001): surgency, defined in terms of approach, high-intensity pleasure, and activity level; negative affectivity, defined in terms of discomfort, fear, anger/frustration, sadness, and low soothability; and effortful control, defined in terms of inhibitory control, attentional focusing, low-intensity pleasure, and perceptual sensitivity. Especially interesting, perhaps, is that these three dimensions are very similar to three of the “Big Five” personality factors (see McCrae & Costa, 1987), with the negative affectivity dimension mapping onto the personality factor of neuroticism, the surgency dimension mapping onto the personality factor of extraversion, and the effortful control dimension mapping onto the personality factor control/constraint (Putnam et al., 2002).

Temperament and Parenting

When it comes to considering how temperament might affect parenting, hypotheses guiding research have been fairly general, and there has been no truly systematic effort to determine the differential influence of any of the sets of temperament dimensions just discussed. In terms of general predictions, it has been expected, for example, that children would be more likely to evoke warm and supportive care when they are easy to soothe, sociable, and adaptable. In contrast, the child who scores high on negative emotionality or is difficult would be expected to evoke less supportive and responsive care, and perhaps even elicit hostile, insensitive parenting, especially when parents confront additional stressors expected to undermine their parental competence. As it turns out, it is the potentially adverse effects of negative emotional characteristics that have received the most attention. The disproportionate interest that has been paid to difficult or negative infant and child characteristics no doubt stems from the prevailing hypothesis that it is hard-to-manage, negatively emotional, and demanding infants, toddlers, and children who are most likely to develop behavior problems, especially of the externalizing variety, in part because of the hostile-intrusive or even detached-uninvolved caregiving they evoke.

A number of investigations do provide evidence linking infant and child negativity/difficulty with less supportive, if not problematic, parenting (e.g., Hemphill & Sanson, 2000; Hinde, 1989; Linn & Horowitz, 1983). One of the more noteworthy studies was conducted by Van den Boom and Hoeksma (1994), who compared the mothering provided to highly irritable and nonirritable newborns across their first 6 months of life (see also Engfer, 1986). Over time, mothers of the irritable infants showed less visual

and physical contact, less effective stimulation, less involvement, and less responsivity to positive signals from their infants. Such findings are consistent with, and reminiscent of, Maccoby, Snow, and Jacklin's (1984) discovery that mothers with more difficult boys became less involved in teaching activities with them across the period from 12 to 18 months of age. They are also in line with recent findings showing that 6-month-olds rated as more temperamentally difficult by their mother receive less affection from their father (Goldberg, Clarke-Stewart, Rice, & Dellis, 2002) and that 3- to 5-year-olds reported as being more (negatively) emotionally intense have a father who takes less responsibility for their care (McBride, Schoppe, & Rane, 2002).

In view of evidence that positive and negative emotionality are separable dimensions of temperament, even in infancy (Belsky, Hsieh, & Crnic, 1996), it is important to note that children who score high on positive affect and self-regulation experience more positively responsive parenting (e.g., Hinde, 1989; Kyrios & Prior, 1990). Fathers of more sociable preschool children, ones who score high on positive emotions, also are more involved with them than are fathers of children who score low on sociability, especially in the case of daughters (McBride et al., 2002).

The fact that most work on effects of child temperament on parenting, including all that just cited, is correlational in nature raises obvious interpretive problems. Instead of child negativity, for example, causally influencing parenting, it could be that the associations detected reflect the role of shared genes in shaping child temperament and parenting behavior. Pike, McGuire, Hetherington, Reiss, and Plomin (1996) were able to overcome this problem using a behavior-genetic-informed research design in their study of adolescents' families with identical and fraternal twins, full sibs, half-sibs, and stepsibs. Even after taking into consideration genetic effects, they found that more negative, irritable, or aggressive children were more likely to receive negative parenting than were other children.

Highlighting even more dramatically the causal role of the child in shaping parenting are the results of some creative experimental investigations. Brunk and Henggeler (1984), for example, trained 10-year-old child confederates to exhibit oppositional or socially withdrawn behavior while playing a board game with women who were mothers, including their own mother. The findings showed that mothers behaved quite differently in the new conditions (compared with pretraining). Using a somewhat different experimental strategy, Anderson, Lytton, and Romney (1986) observed mothers of normal and conduct-

disordered children interacting with their own child, someone else's normal child, and someone else's disordered child. The data revealed a substantial effect of deviant child behavior on maternal functioning. Barkley and Cunningham (1979) and Schachar, Taylor, Wieselberg, Thorley, and Rutter (1987) were able to demonstrate much the same thing by taking advantage of stimulant medication to alter child hyperactive behavior.

Despite the impression left by this rather brief summary of relevant research suggesting perhaps strong effects of temperament on parenting, beginning in the 1st year of life, it is critical to note that the overall corpus of relevant data is by no means consistent. Indeed, when Crockenberg (1986) reviewed 16 studies examining the proposition that infant negativity would be related to lower levels of maternal sensitivity almost 2 decades ago, she found that nine investigations yielded evidence consistent with the hypothesis, but that seven supported its converse, namely, that mothers of highly irritable infants are more positive and show more commitment when interacting with their babies! In the time since Crockenberg's review, inconsistent results have continued to be reported (Crockenberg & Leerkes, 2003a), with some showing that infant difficulty predicts less sensitive, supportive, and/or responsive mothering (R. Clark, Hyde, Essex, & Klein, 1997; Hagekull & Bohlin, 1986; Spangler, 1990), others showing that difficult infants experience more such parenting (Mangelsdorf, Gunnar, Kestenbaum, Lang, & Andreas, 1990; Seiffer, Schiller, Sameroff, Resnick, & Riordan, 1996; Washington, Minde, & Goldberg, 1986; Zahr, 1991), and still others failing to chronicle either positive or negative associations between measures of infant negativity and maternal behavior (P. R. Butcher, Kalverboer, Minderaa, Van Doormaal, & Ten Wolde, 1993; Fish & Stifter, 1993; Hagekull & Bohlin, 1986). These inconsistencies do not seem to be a simple function of variation in how temperament has been measured, how parenting has been assessed, or the age at which either have been evaluated (Crockenberg & Leerkes, 2003a; Pauli-Pott, Mertesacker, Bade, Bauer, & Beckmann, 2000).

Temperament in Context

Should this pattern of inconsistency lead to the conclusion that temperament does not affect parenting? Yes, perhaps, if only main effects of temperament are being entertained, but clearly otherwise if the effects of temperament are considered in the context of other factors that impinge on parenting. That is, seemingly inconsistent findings may reflect

the fact that the impact that temperament has on parents varies as a function of other factors that shape parenting. A characteristic of the child that might have one consequence for parenting under one condition could have none—or even the opposite—under another (Crockenberg, 1986). Several strands of evidence suggest this to be the case. In what follows, we consider factors that Belsky (1984) included in his process model of the determinants of parenting.

We begin by considering interactions between one child characteristic, difficult temperament/negative affectivity, and another, child gender. Results from several investigations suggest that parents are more accepting of negative emotionality and difficulty in boys than in girls (Putnam et al., 2002). Consider in this regard B. Gordon's (1983) finding that whereas mothers gave more commands to 2- to 4-year-old daughters who were difficult, they directed more commands at sons who were easy (Rubin, Hastings, Stewart, Henderson, & Chen, 1997); discovery that greater emotion dysregulation predicted more warmth by mothers in the case of sons but not daughters; Rendina and Dickersheid's (1976) observation that fathers were more socially interactive with difficult sons and less interactive with difficult daughters; and Lamb, Frodi, Hwang, Forstromm, and Corry's (1982) fathering research showing men to be less involved with daughters who evinced high levels of negative affect and low levels of positive affect, but less involved with sons who manifested a more easy temperament.

As it turns out, it is not universally the case that the kind of gender-moderated findings just summarized emerge from investigations that look for them. In a study of infant irritability and mothering, Crockenberg (1986) found mothers to be less responsive to the crying of irritable boys than of girls. And in the aforementioned work by Maccoby et al. (1984), it was observed that resistant, hard-to-soothe girls evoked more maternal teaching effort than easy girls, with the reverse being true for boys. Exactly why such inconsistencies emerge in the literature remains unclear, but the possibility of random variation should be discounted. Nevertheless, the results, however inconsistent, highlight the need to consider child gender when examining effects of temperament on parenting behavior.

Characteristics of the parent may also interact with child temperament to predict child rearing. Teti and Gelfand (1991) argued, for example, that it was principally when maternal self-efficacy was low that their infants' fussy difficultness resulted in less warmth, engagement, and sensitivity. Not inconsistent with this view are results from Pauli-Pott et al.'s (2000) study of more than 100 Ger-

man mother-infant pairs, which revealed that high levels of infant negativity predicted less sensitive mother-infant interaction only when mothers showed high levels of depression. But it may not just be clinically relevant psychological states that interact with temperament in predicting parenting. L. A. Clark, Kochanska, and Ready (2000) found negative temperament to predict increased use of power assertion by mothers who scored high (but not low) in extraversion. And recent research by Crockenberg and Leerkes (2003b) and by Calkins and associates (cited in Crockenberg & Leerkes, 2003a) indicates that it may also be when mothers score low in self-efficacy that high levels of distress to limits on the part of infants is most likely to result in lower levels of sensitive/supportive care than would otherwise have been expected.

The broader social context in which parents care for their children may also need to be considered when it comes to understanding the effect of temperament on parenting. In this regard, social support was singled out by Crockenberg and McCluskey (1985) in their study of mother-infant interaction, on finding that neonatal irritability predicted less maternal sensitivity when infants were 1 year of age, but only when mothers reported that levels of social support were low. Also noteworthy are recent findings from work focused on more than one child in a family (Jenkins, Rasbash, & O'Connor, 2003). In this population-based investigation of Canadian 4- to 11-year-olds, greater child negativity predicted greater parental negativity, but it was also found that this child effect was amplified when families were economically disadvantaged. These results, consistent with some of the other findings reviewed, are in accord with the notion of cumulative risks, in that it is not so much a single risk factor, such as a difficult temperament, that may undermine parental competence and sensitivity, but rather the accumulation of risks (Belsky, 1984).

But context can operate in ways that are not easily assimilated into notions of cumulative risk. Consider in this regard the intriguing data from X. Chen et al. (1998), who found, as predicted, that whereas high levels of inhibition predicted less parental acceptance and encouragement of achievement and greater inclination to use punishment in a Canadian sample, this same child attribute predicted high maternal acceptance and encouragement of achievement and less rejection in a Chinese sample. In explanation of these results, the investigators noted that Chinese culture highly values inhibition and reticence, an orientation that is rather foreign to most North Americans, who place great store in being outgoing and sociable. In a sense, then,

Thomas et al.'s (1963) notion of goodness of fit would seem to account for the results under consideration, though the fit has more to do with culturally approved values of parents in the East and West than with particular characteristics of one parent versus another within the same culture.

PARENT'S DEVELOPMENTAL HISTORY

As noted earlier, the classic explanation of child maltreatment highlighted the adverse rearing experiences that abusive and neglectful parents themselves received while growing up in their family of origin. As such, this etiological perspective underscored the importance of parents' own developmental histories, especially their experiences being parented as children, when it comes to understanding why parents parent the way they do. In this section devoted to the role of developmental history, and most especially child-rearing history, in shaping parenting, we first consider evidence and arguments pertaining to child abuse and neglect per se before turning attention to parenting that is not so labeled, including harsh punishment in general and more positive aspects of parenting.

The Intergenerational Transmission of Child Maltreatment

During the 1970s, two of the clinicians at the forefront of inquiry into the etiology and sequelae of child maltreatment observed that "the most constant fact [concerning child abusers] is that parents themselves were nearly always abused or battered or neglected as children" (Fontana, 1973, p. 74) and that "we see an unbroken line in the repetition of parental abuse from childhood into the adult years" (Steele, 1976, p. 15). More than 30 years after these comments were made, there are few in the scientific community who would endorse them in their entirety (Belsky, 1993; Cicchetti & Toth, 1998; Oliver, 1993). Despite the abundance of evidence and reports linking the perpetration of child abuse and neglect with a childhood history of victimization (e.g., Altemeier, O'Connor, Vietze, Sandler, & Sherrod, 1984; Heyman & Slep, 2002; Whipple & Webster-Stratton, 1991), scholars have been all too aware for decades now of the inherent limitations of much of the available data (Belsky, 1980, 1993; Cicchetti & Rizley, 1981; Kaufman & Zigler, 1987; Widom, 1989). Most noteworthy, perhaps, have been the excessive reliance on retrospective reports, once perpetrators have been labeled as maltreaters; small clinical

samples, all too often without adequate control groups; and data collectors not blind to parents' maltreatment status. A recent report addressing the specific issue of the validity of adult retrospective reports of adverse childhood experiences underscores concerns about evidence emanating from respondents' memories of their childhood. Hardt and Rutter's (2004) analysis of studies published between 1980 and 2001, in which there was a quantified assessment of the validity of retrospective recall of sexual abuse, physical abuse, physical/emotional neglect, or family discord, revealed that although retrospective reports of major adversities of an easily defined kind are not severely biased (e.g., parental death, father goes to war), the same cannot be said of reports pertaining to the quality of parenting experienced or of family relations more generally: "Little weight can be placed on the retrospective reports of details of early experiences or on reports of experiences that rely heavily on judgment or interpretation" (p. 260).

Despite the acknowledged limits of *much* of the relevant literature, it is noteworthy that a few well-designed, prospective studies clearly document a linkage between a *reported* history of childhood maltreatment and the *subsequent* perpetration of maltreatment (e.g., Egeland, Jacobvitz, & Papatola, 1987; Hunter & Kilstrom, 1979) and thereby underscore the significance of a parent's developmental history in shaping his or her parenting. One recent study, in fact, demonstrates that the more severe the physical abuse experienced (and reported by children), the more likely the next generation of children would report that they, too, had been subject to physically abusive parenting (Pears & Capaldi, 2001). More than a decade ago, the data were of sufficient quality that Belsky (1993) was led to question the much-cited conclusion of one set of distinguished scholars that "the time has come for the intergenerational myth to be placed aside" (Kaufman & Zigler, 1989, p. 135). Such questioning would seem especially appropriate because "countless studies" show that "antisocial behavior patterns are passed from one generation to the next at a rate well beyond chance," even after controls for confounding factors like family size, area of residence, and rates of criminal behavior have been implemented (Wahler & Dumas, 1986, p. 50).

Upon noting that among better-designed studies using standardized self-report measures (e.g., written questionnaires, structured interviews) and reasonably selected comparison groups consistent differences emerge in the developmental histories of index and control samples, Kaufman and Zigler (1987) estimated the actual rate of intergenerational transmission to be only 30% (plus or

minus 5%), given a range in rates between 7% (Gil, 1971) and 70% (Egeland & Jacobvitz, 1984) chronicled in the literature. Thus, *only* about one-third of individuals who were abused or neglected will maltreat their own children. Such an estimate is not inconsistent with Oliver's (1993, p. 1315) subsequent conclusion that "one-third of child victims grow up to continue a pattern of seriously inept, neglectful, or abusive rearing as parents." Thus, although the intergenerational transmission of child maltreatment is by no means inevitable, the estimated rate still suggests that an adult's own child-rearing history may play a significant role in shaping his or her own parenting. Moreover, what remains most disconcerting about the Kaufman and Zigler (1987, 1989) analysis was the failure of these scholars to take into consideration the developmental status of the children under study (Belsky, 1993). For example, in discussing the results of Hunter and Kilstrom's (1979) prospective follow-up of at-risk and comparison mothers 1 year after the birth of their child, Kaufman and Zigler (1989, p. 132) described a parent whose child had not been identified as maltreated as one "who broke the cycle of abuse." What they apparently failed to realize—or at least acknowledge—was that although only 19% of the at-risk parents in the Hunter and Kilstrom investigation maltreated the study child, those who were assumed to have broken the cycle had many more years to care for the study child, to say nothing of other children (including those not yet born).

There would seem to be other fundamental problems with conclusions based on the available data. Especially important are limitations in data that lead some to conclude that "the majority of abusive parents were not abused in their own childhoods" (Widom, 1989, p. 8). Although this may indeed turn out to be the case, it seems risky to embrace such a viewpoint without simultaneously acknowledging that retrospective reports of childhood experience can be inaccurate not only because of overreporting of maltreatment, but because of underreporting as well. As clinicians, attachment researchers, and cognitive scientists know, painful experiences in childhood are often excluded (unconsciously) from memory (Bowlby, 1980; G. Goodman, Emery, & Haugaard, 1998; Main, Kaplan, & Cassidy, 1985).

It thus remains all too conceivable that certain individuals who report no history of maltreatment simply cannot recollect their troubled childhood. In consequence, before any empirical estimates are taken at their face value, two things need to be acknowledged. The first is that a parent who has not mistreated a single 1-, 2-, or 3-year-old might still mistreat that child at an older age—or another child.

The second is that some parents with problematical developmental histories who contend they were not mistreated may not have access to the very memories required to respond accurately to the relevant inquiries. All this is not to argue that every mistreated child grows up to be a maltreating parent, or even that only individuals with histories of maltreatment will mistreat their own offspring (though this is a hypothesis that needs serious testing by means of skilled clinical interviews). As Kaufman and Zigler (1987, p. 190) themselves noted, even though "being maltreated puts one at risk for becoming abusive . . . the path between these points is far from direct or inevitable." What, though, determines whether or not a victim of maltreatment will grow up to become a perpetrator? To answer this question, it is useful to consider some of the possible psychological and behavioral mechanisms presumed to be responsible for transmission when it does occur.

Mechanisms of Transmission

Several mediating processes, none of which are mutually exclusive, may account for the intergenerational transmission of child maltreatment (Kaufman & Zigler, 1989; Simons, Whitbeck, Conger, & Chyi-In, 1991; van Ijzendoorn, 1992). The most obvious simply presumes that aggressive, antisocial behavior is learned in childhood and expressed in adulthood in the parenting role. Several types of learning can be distinguished, including modeling, direct reinforcement, and coercion training (in which escalating negative behavior is inadvertently rewarded when a parent gives up on trying to control a child who has responded adversely to the parent's own aversive behavior).

In addition to learning particular behaviors in childhood that are repeated in adulthood, intergenerational transmission may involve parents' philosophies of discipline. Thus, Simons et al. (1991) theorized and found in their study of the harsh parenting of early adolescents that a belief in the legitimacy of strict, physical discipline mediated (in part) the linkage between the experience of harsh discipline in childhood and its perpetration when an adult. Social-cognitions theorists emphasize the importance of ideas about parenting, especially attitudes and values toward the use of physical punishment (Deater-Deckard, Lansford, Dodge, Pettit, & Bates, 2003; Dodge, Bates, & Pettit, 1990), and point to a wealth of data showing that adults who have been spanked in childhood are more accepting of the use of corporal punishment (e.g., Bower-Russa, Knutson, & Winebarger, 2001; Deater-Deckard et al., 2003). Notable as well is evidence that by middle childhood, a link exists between past discipline

experiences and current attitudes toward physical punishment (Holden & Zambarano, 1992), an association still in evidence to some degree during early adolescence (Deater-Deckard et al., 2003) and among college students (Bower & Knutson, 1996).

The effect of mistreatment in childhood may be more general than presumed by social learning theories focused on specific parenting behaviors or theories of social cognition emphasizing beliefs about discipline. In light of evidence that maltreated children have problems with emotion regulation, aggression, and empathy (for review, see Cicchetti & Lynch, 1993; Cicchetti & Toth, 1998), it seems plausible that abusive and neglectful childhoods may promote hostile personalities that become a proximate cause of maltreatment. Certainly, the data to be reviewed in the next two major sections of this chapter dealing with parental psychopathology and personality are not inconsistent with this mechanism of influence. Moreover, support for it emerged in the aforementioned study by Simons et al. (1991) after taking into consideration unmediated linkages between harsh parenting across generations as well as the mediating influence of parental disciplinary beliefs (see also Levendosky, Hutch-Bocks, Shapiro, & Semel, 2003). Several recent prospective studies document the role by “angry, aggressive behavior” (Conger, Nell, Kim, & Scaramella, 2003), “antisocial behavior” (Capaldi, Pears, Patterson, & Owen, 2003), and “adolescent delinquency” (Thornberry, Freeman-Gallant, Lizotte, Krohn, & Smith, 2003) in mediating the intergenerational transmission of parenting (Serbin & Karp, 2003). Notably, all of these investigations measured harsh parenting during adolescence, and then 5 to 10 years later measured the problematic parenting of the now grown-up adolescents who had young children. The fact that some of these investigations focused on mothers and fathers (Thornberry et al., 2003) or relied on observational assessments of parenting (in both generations; Capaldi et al., 2003; Conger et al., 2003) highlights the robust nature of the mediational effect under consideration. What these investigations could not determine, however, was the potential role that shared genes play in both the intergenerational continuity of parenting and the mediational effect of adolescent problem behavior (Serbin & Karp, 2003).

Not unrelated to the notion of general personality when it comes to conceptualizing the developmental process by which parenting is intergenerationally transmitted is the concept derived from attachment theory of an “internal working model.” As van Ijzendoorn (1992, p. 79) observes, according to this perspective,

The parents’ experiences with grandparental responsiveness, rejection, or ambivalence lead to an internal representation of the grandparent as (un-)responsive to the parental needs, and it is hypothesized that this internal representation will influence the degree of responsiveness the parents are able to show toward their children (Bowlby, 1988; Main et al., 1985). Parents who experienced a high degree of responsiveness in childhood are supposed to be more open to signals and needs of their infants than rejected or ambivalently treated parents, because the former parents are more able to take their children’s perspective and to not feel threatened by signs of anxiety in their children. (Main et al., 1985)

In line with such theorizing, Crittenden (1985, p. 1301) noted, after observing various types of parents interacting with their young children, that

abusing parents behaved as though they perceived the world from an adversarial perspective, one that demanded that they establish control in order to satisfy wants that must be imposed on others in spite of objection. . . . Neglecting mothers behaved as though they did not believe that relationships could meet their needs or that they could effectively elicit a satisfying response; their model was one of emptiness and depression.

Subsequent work by Crittenden, Partridge, and Clausen (1991) further revealed that maltreating parents and their partners had rates of insecure working models of attachment (i.e., dismissing, preoccupied) in excess of 90%!

Breaking the Cycle: Lawful Discontinuity in Development

It is especially noteworthy that from the perspective of attachment theory, even though (some) intergenerational transmission of maltreatment is expected, it is by no means considered inevitable. Critical here is the theoretical proposition that child abuse and neglect will be intergenerationally transmitted when early negative experiences are not remembered or integrated into revised working models of relationships (Bowlby, 1980). Certainly consistent with this view are Main and Goldwyn’s (1984) findings that women who remembered their mother as rejecting and their childhood as troubled but who had formed coherent accounts of them were *not* likely to reject their children. This contrasted markedly with the parental functioning of mothers who had yet to come to grips with their problematic childhoods.

That attachment theory provides a theoretical basis for the conditions under which, and the mechanisms by which, child maltreatment is not transmitted across generations

represents one of its major strengths as a tool for understanding the determinants of parenting in general and the etiology of child maltreatment in particular. Especially intriguing, therefore, are the findings from several investigations that accord with theoretical tenets of attachment theory when it comes to accounting for "lawful discontinuity" in parenting across generations (Belsky & Pensky, 1988). In two separate, prospective studies of at-risk mothers followed from the postpartum period, it was found that parents with histories of maltreatment who did not maltreat their own children (during the study period) had more extensive social supports, had experienced a nonabusive and supportive close relationship with one parent while growing up, or were more openly angry and better able to give a detailed and coherent account of their earlier abuse than were repeaters (Egeland et al., 1987; Hunter & Kilstrom, 1979). Additionally, Egeland et al. found that involvement with a supportive spouse or boyfriend or a positive experience in therapy characterized the nonabusing parents with at-risk developmental histories. Such findings are consistent with Caliso and Milner's (1992) report showing that among mothers at risk for maltreating their offspring due to a history of abuse in their own childhood, those who did not abuse were involved in more satisfying interpersonal relationships than those who did. All these experiences are of the kind postulated by attachment theory to modify the internal working model, or representations and interpersonal expectations, of individuals with seriously troubled parent-child relationship histories and so enable them to care for their own offspring in a manner decidedly different from the way they themselves were cared for.

This interpretation also seems useful in understanding the results of an English study that did not focus on abuse and neglect *per se* but identified conditions that led some women with a problematic childhood (due to family conflict and institutional rearing) not to provide the low quality of care (hostility, rejection, spanking) that was generally characteristic of mothers with such histories. The women who broke the cycle in this instance tended to be married to supportive and nurturing men, thus suggesting that "the spouse's good qualities exerted a powerful ameliorating effect" on the parental functioning of women known to be at risk as a result of their developmental history (Quinton, Rutter, & Liddle, 1984, p. 115). Interestingly, in a study of teenage mothers with a history of parental rejection, Crockenberg (1987b) also found that support from a partner forecast less angry and punitive care toward a toddler than otherwise would have been expected. And, finally, Belsky, Pensky, and Youngblade

(1990) observed that the ameliorating influence of a positive partner relationship on negative parenting in the case of mothers with negative childhood experiences also was discernable in a nonrisk sample.

The common denominator in all of these inquiries seems to be emotionally supportive relationship experiences that function (apparently therapeutically) to modify, presumably, the feelings and expectations of these women. Whether these effects occur in the case of men remains unknown. Unknown, too, is the exact process—or processes—of influence. Is it the case, for example, that internal working models have actually been modified, as just theorized? Are actual parenting philosophies influenced? And what is the exact route by which parenting behavior is altered? Egeland et al.'s (1987) findings suggest that a conscious resolve not to repeat a history of abuse characterizes nonrepeaters, but under what conditions is such resolve sufficient? In any event, what these breaking-the-cycle investigations underscore is a core notion central to Belsky's (1984) determinants of the parenting model: that sources of risk can be buffered by sources of support. Or, to use Cicchetti's (Cicchetti & Rizley, 1981) terminology, protective factors can reduce the impact of risk factors. That is, it remains unlikely that any single factor will determine the course of a parent's child-rearing behavior, as parenting is multiply determined, with forces of influence that encourage growth-promoting parenting capable of off-setting the risks associated with forces that conspire against such child-rearing behavior.

Reflection on the breaking-the-cycle investigations and their findings also raises questions concerning which at-risk parents will be fortunate enough to experience "emotionally corrective" close relationships—either with a nonabusive parent, close friend, therapist, or spouse—and why. The work of Rutter and his colleagues (Quinton et al., 1984) suggests that self-efficacy-promoting experiences associated with schooling (academics, extracurricular activities) were important for determining which mothers-to-be married "better" men who would provide the emotional support that proved so beneficial to them. Thinking developmentally, though, we can still ask what led some girls to have more positive schooling experiences than others. Might it have been an early supportive relationship that led them to trust others or to develop interpersonal skills? Might physical attractiveness have had something to do with it? Two studies call attention to this latter possibility. In one, Elder, Van Nguyen, and Caspi (1985) found that hostile men who lost their jobs were less likely to treat their daughters harshly if the girls were attractive. In the other,

Belsky et al. (1990) found that the very women with negative histories who were in a happy marriage and were not negative to their 3-year-old were more physically attractive than women with equally negative histories who were negative toward their preschoolers and who were not in a happy marriage. Such findings raise the suspicion that the beneficial effect of a supportive mate in breaking the intergenerational transmission process may be driven, at least in part, by features of the woman herself.

This discussion is not meant to imply that physical attractiveness is *the* important factor when it comes to determining which women at risk for mistreating their children end up not doing so because they somehow secure emotionally corrective relationship experiences. Rather, it is intended to highlight the fact that far more needs to be understood about who obtains the social-emotional support that seems so important, if not critical, for disrupting the intergenerational transmission process and about the exact processes through which the ameliorative effect is exerted. These comments notwithstanding, it is clear from these inquiries, even more so than from the difficult-to-interpret data about actual rates of intergenerational transmission, that even though a history of maltreatment is a risk factor of “considerable” (Kaufman & Zigler, 1989, p. 135) significance in the etiological equation, some—perhaps many, even most—parents do not repeat the cycle of maltreatment.

Parenting across Generations (in the “Normal” Range)

As some of the work cited in the preceding subsections indicates, not all research on the potential influence of child-rearing history on parenting has focused on child maltreatment per se (Serbin & Karp, 2003). Some of it has examined “harsh parenting,” which, at the extreme, becomes very much like child abuse, even if it is not so labeled (e.g., Capaldi et al., 2003; Conger et al., 2003; Crockenberg, 1987a; Simons et al., 1991; Thornberry et al., 2003). But some of it focuses on more positive aspects of parenting (Z. Chen & Kaplan, 2001; Smith & Farrington, 2004). Like virtually all work on the intergenerational transmission of child maltreatment, much of this nonmaltreatment research relies on retrospective reports of the child rearing experienced by parents while growing up in their family of origin, or some variation on that theme; this state of affairs is changing, however, as children studied as adolescents are followed up as young adult parents (Capaldi et al., 2003; Z. Chen & Kaplan, 2001; Conger et al., 2003; Smith & Farrington, 2004; Thornberry et al., 2003). In some studies,

retrospective reports are provided by grandparents about the way they parented their now adult children (e.g., Wintre & Dhimi, 2003) and in others by parents on the way they were reared as children or adolescents (e.g., Baydar, Reid, & Webster-Stratton, 2003; Bluestone & Tamis-LeMonda, 1999), sometimes assessed prior to the birth of a child (Crockenberg & Leerkes, 2003b; Feldman, Curran, Jacobvitz, Boyd-Soisson, & Jin, 2003). In some of the research on the intergenerational transmission of parenting, whether based on retrospective or prospective data, the parenting to be explained is observed (e.g., Baydar et al., 2003; Biringen, 1990; Capaldi et al., 2003; Conger et al., 2003; Meyers, 1999), whereas in other cases, it is reported by parents themselves (e.g., Z. Chen & Kaplan, 2001; Meyers, 1999; Thornberry et al., 2003) or by their children (e.g., Muller, Hunter, & Stollak, 1995).

Whereas most of the research that relies on retrospective assessments of parenting experienced while growing up (or provided by the grandparent when the parent in question was a child) employs brief and easy-to-complete, survey-research type instruments, this is not the case with one body of research that derives directly from mainstream attachment theory (rather than more general learning theories of the origins of parenting). When it comes to examining the intergenerational transmission of parenting (and a host of other developmental questions), many attachment researchers employ the Adult Attachment Interview (AAI). This clinical interview consists of 18 questions and is structured entirely around the topic of attachment, principally the individual’s relationship to the mother and father during childhood (see Hesse, 1999). Interviewees are instructed to describe their relationships with their parents and to provide specific biographical episodes to substantiate global evaluations. Thus, individuals who report that their parent was very generous with them or highly affectionate toward them are asked to recall specific incidents of such behavior. Interviewees are asked directly about childhood experiences of rejection, being upset, ill, and hurt, as well as about loss, abuse, and separations. They are also asked to offer explanations for their parent’s behavior and to describe their current relationships with their parents and the influence they consider their childhood experiences exerted on their development. The interview is designed to evoke not so much the adult’s actual, veridical experiences in childhood but, rather, their reconstructions of the meaning and mental representations of early experiences.

The tape-recorded interview is transcribed by a typist, and, on the basis of the information obtained from the AAI, a specially trained evaluator rates the subject on a series of

rating scales (e.g., role reversal: the extent to which the respondent parented the parent during childhood; idealization: the extent to which the respondent idealizes his or her parent; preoccupied anger: the extent to which the respondent is still very angry at the parent; inability to recall: the extent to which the respondent cannot remember events and experiences from childhood). These ratings, coupled with the evaluator's general sense of the entire transcript, especially how coherent (i.e., organized and integrated) it is, lead the evaluator to characterize the respondent's state of mind regarding attachment (i.e., internal working model) using a limited set of classification categories. Ultimately, the coding of AAI transcripts is based not on the participants' description of childhood experiences per se, but on the way these experiences and their effects on current functioning are reflected on and evaluated. It is significant that attachment classifications based on the AAI have been found to be independent of general intelligence and verbal ability (for review, see Hesse, 1999).

The *secure-autonomous* state of mind is reflected in an individual's inclination to value attachment relationships and regard attachment-related experiences as developmentally influential. In the course of the AAI, such persons appear self-reliant, objective and nondefensive. It is noteworthy that persons receiving this classification either convincingly describe a history of emotionally supportive relationship experiences or provide evidence that they have come to terms with a childhood lacking in them, thus permitting a balanced view of relationships.

Adults classified as *insecure-dismissing* have a tendency to deny negative experiences and emotions or to dismiss their developmental significance. These individuals can remember little and seem unable to reevoked the feelings associated with the experiences they do recall. Often, they offer an idealized picture of parent or parents but, in response to probes eliciting evidence to substantiate generalizations, may recall experiences quite inconsistent with their positive, global appraisals. For example, in response to a follow-up query from the interview asking for details about how a parent was generous, the respondent ends up talking about a parent's failure to attend his or her birthday party or his or her disappointment with a present received from a parent. Insecure-dismissing individuals present themselves as strong, independent people for whom closeness and attachment mean little. The defensive flavor of the detached pattern is reminiscent of the insecure-avoidant infant pattern.

Adults classified as *insecure-preoccupied* demonstrate a continuing involvement of preoccupation with their par-

ents. They appear confused, incoherent, and unobjective regarding relationships and their influences on them. Anger over the past and present seems not to be resolved but, instead, to be a major organizing theme of their current relationships with their parents. These individuals seem caught up in their early relationships, with little ability to move beyond them.

In the main, and rather consistently, research that relies on retrospective assessments of parenting reveals positive associations between parenting across generations (and so, too, do the more recent prospective studies; see later discussion): Supportive and/or authoritative parenting tends to predict supportive/authoritative parenting, whereas authoritarian and/or harsh parenting tends to predict authoritarian/harsh parenting. This pattern can be seen consistently in AAI-based research. Parents with secure attachments are more sensitive to their children than parents with dismissing or preoccupied attachment (Aviezer, Sagi, Joels, & Ziv, 1999; George & Solomon, 1996; Ward & Carlson, 1995). Some research has found that the caregiving of parents with secure attachment encouraged learning during teaching tasks (Crowell & Feldman, 1988; van Ijzendoorn, 1992) and that secure parents respond to their infants' affect in flexible ways (Haft & Slade, 1989). In contrast to mothers with secure attachments, those with dismissing attachments are less supportive and colder in interactions with their children (Crowell & Feldman, 1988, 1989). Preoccupied parents are found to be inconsistent in their parenting (Crowell & Feldman, 1988, 1989; Haft & Slade, 1989); they may alternate between secure-like parenting or controlling, confusing, and less sensitive parenting (van Ijzendoorn, 1995; Ward & Carlson, 1995). Some of the non-AAI work that is longitudinal in design also indicates, as noted already, that much, even if not all, of the intergenerational transmission of problematic parenting is mediated by problem behavior during adolescence (Capaldi et al., 2003; Conger et al., 2003; Serbin & Karp, 2003; Thornberry et al., 2003).

Whether assessed using brief survey questionnaires or the more lengthy and clinically sensitive AAI, studies of the intergenerational transmission of parenting based on retrospective reports produce associations of only modest size in parenting across generations, either because these are error-prone for reasons of memory distortion, as discussed earlier, or due to undetected—and unexamined—processes of lawful discontinuity. Recently, in fact, elements of the AAI have been called into question, basically because prospective data collected as part of a 20-year longitudinal study did not show that individuals classified on the AAI as secure but

who reported—and supposedly overcame—problematic child-rearing histories (i.e., “earned secures”) actually experienced more negative child-rearing experiences than age-mates also classified secure but who did not report such adverse developmental experiences (Roisman, Padron, Sroufe, & Egeland, 2002). Ultimately, whatever the instrumentation, there will always be reasons to be cautious about embracing findings derived from retrospective reports of parenting. Fortunately, several interesting prospective studies can be singled out that actually include measurements of child rearing obtained during childhood/adolescence and of parenting secured during adulthood. As we will see, these studies, which yield results one can place more confidence in, generate findings not inconsistent with those emanating from most retrospective studies.

Elder and associates (1985) took advantage of the multi-generational Berkeley Growth Study to examine whether, and even how, the parenting that a parent experienced while growing up predicted the parenting that the parent provided as an adult. Of particular importance, although not all the data were prospective in the sense defined earlier, some data were. Longitudinal analysis revealed that growing up in a home in which parents’ personalities could be described as unstable and in which parental care could be depicted as controlling, hostile, and lacking in affection led to the development of unstable personalities in these children as adults. Such psychological instability on the part of Berkeley parents, derived as it seemed to be from poor developmental experiences in the family of origin, itself proved predictive of tension in their own marriage. And marital tension, in the face of another generation of personal instability, contributed to extreme and arbitrary discipline for the third generation of Berkeley children. Moreover, exposure to such care resulted in the development of behavior problems in this third generation that proved predictive of undercontrolled behavior in adulthood. Thus, parenting difficulties, apparently originating from personality problems, seemed to leave a legacy of personal adjustment problems that were passed down through parenting from one generation to the next, testimony indeed for the role hypothesized for personality in Belsky’s (1984) model (shaped in part by this work) in mediating between developmental history and parenting. Using a large sample of Iowa farm families experiencing financial stress due to poor macroeconomic conditions, Simons and associates (1991) report similar evidence showing, on the basis of retrospective reports of child-rearing history, that harsh parenting is intergenerationally transmitted via its impact on hostile personality. And, as already noted, three recent prospective studies that followed up adolescents when they

were young parents provide additional supportive evidence of the mediational role of angry, aggressive, and antisocial personality characteristics and behavior in the intergenerational transmission of problematic parenting (Capaldi et al., 2003; Conger et al., 2003; Serbin & Karp, 2003; Thornberry et al., 2003).

But it looks like it is not just problematic parenting that can be expected to undermine the child’s developmental competence which is passed on down the generations, but more growth-promoting parenting as well (Serbin & Karp, 2003). Z. Chen and Kaplan (2001) took advantage of a 2-decade longitudinal study and were able to link parenting measured during the childhoods of parents with the parenting they actually provided their own offspring. More specifically, children’s reports of the parenting they received as seventh graders were used to predict the parenting they reported providing when in their mid- to late-30s to their own offspring. Structural equation modeling showed that higher levels of good parenting (e.g., parental acceptance, living in a happy home) experienced in childhood forecast the provision of higher levels of “constructive parenting,” defined in terms of monitoring, communication, involvement in child’s education, affection, and discipline (e.g., use of praise and reasoning). The fact that the linkage over time between parenting experienced in childhood and parenting provided in adulthood was only modest calls attention to the need to understand the developmental processes that break the cycle not only of child maltreatment or harsh parenting, but also of supportive parenting. After all, in the same way that it makes sense to ask under what conditions and through what mechanisms does problematic parenting in one generation not lead to problematic parenting in the next, one can wonder when and why supportive parenting in one generation does not promote similarly supportive parenting in the next. Fortunately, in the next few decades, any number of longitudinal studies initiated in the 1970s, 1980s, and 1990s should be in position, given ongoing follow-ups, to provide data on these and related topics concerning the role of child-rearing history in shaping parenting practices in adulthood.

PARENTAL PSYCHOPATHOLOGY

Most mental disorders show considerable continuity across generations. Whereas many disorders are heritable to some degree, genetic accounts do not fully explain why children whose parents have a history of psychiatric disorder are themselves at risk for psychopathology. In trying to under-

stand how mental disorder is transmitted from one generation to the next, researchers have observed that psychiatric illness can adversely affect parent-child relations and that this may be one of the mechanisms by which risk for psychopathology is passed on from parent to child (S. H. Goodman & Gotlib, 1999). In this section, we consider how Major Depressive Disorder, alcohol abuse and dependence, Antisocial Personality Disorder, and Schizophrenia affect parents' attitudes about and interactions with their children. We restrict ourselves to these conditions, as these are the ones that have been most intensively (and productively) studied in terms of parenting. Reflecting the literature on parenting more generally (Tamis-LeMonda & Cabrera, 2002), the reviewed research focuses primarily on mothers (although the literature on parents with alcohol use disorders provides an exception; Connell & Goodman, 2002; McMahon & Rounsaville, 2002; Phares, 1992; Phares & Compas, 1992). For a more extensive review on parental psychopathology, see Zahn-Waxler, Duggal, and Gruber (2002).

Depression

Mood disorders include Major Depressive Disorder (MDD), Dysthymic Disorder, and Bipolar Disorder. Given the paucity of research on how Dysthymic and Bipolar Disorders affect parenting, the focus here is on parents with MDD. According to the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV), the essential feature of a major depressive episode is a period of at least 2 weeks during which there is either depressed mood or the loss of interest or pleasure in nearly all activities. MDD is more common in women than in men. The lifetime risk for MDD in community samples ranges from 10% to 25% for women and from 5% to 12% for men (American Psychiatric Association, 2000).

Children whose parents are depressed are at risk for a range of adverse outcomes, including problems in self-regulation, peer relationships, and sleep regulation, attachment difficulties, behavioral and affective disorders, and academic difficulties (see reviews by Cummings & Davies, 1994; Downey & Coyne, 1990; Herring & Kaslow, 2002; Teti, Gelfand, & Pompa, 1990). Exposure to a depressed mother's negative cognitions, affect, and behavior is hypothesized to increase children's risk for problem behaviors (S. H. Goodman, Adamson, Riniti, & Cole, 1994).

Maternal Cognitions and Affective Style

Compared to well mothers, mothers with diagnoses of depression make more hostile and critical statements about

their school-age children (Brennan, Hammen, Katz, & Le Brocque, 2002;¹ S. H. Goodman et al., 1994; Hamilton, Jones, & Hammen, 1993), although depressed and well mothers have been shown to be similar in the proportion of neutral or positive statements they make (S. H. Goodman et al., 1994). Depressed mothers are more likely than well mothers to attribute their young children's developmental outcomes to uncontrollable factors, such as genetic inheritance and biology, although they appear to be equally satisfied with their children's development (Kochanska, Radke-Yarrow, Kuczynski, & Friedman, 1987).

Parent-Child Interaction

Observational and self-report data suggest that maternal depression is associated with suboptimal parent-child interactions from infancy into adolescence. In infancy, depressed mothers tend to have difficulties responding contingently and sensitively to their infants, providing optimal levels of stimulation, or engaging their child's attention (Breznitz & Sherman, 1987; Carter, Garrity-Rokous, Chazan-Cohen, Little, & Briggs-Gowan, 2001; Jameson, Gelfand, Kulcsar, & Teti, 1997; Murray, Fiori-Cowley, Hooper, & Cooper, 1996; Stein et al., 1991). They show less positive and more negative affect when interacting with their infants (Campbell, Cohn, & Meyers, 1995; Cohn, Campbell, Matias, & Hopkins, 1990; Cohn, Matias, Tronick, Connell, & Lyons-Ruth, 1986; Dawson et al., 1999; Field, Healy, Goldstein, & Guthertz, 1990; Field et al., 1985, 1988; Teti et al., 1990), and they and their infants more frequently match each other's negative states while less frequently matching each other's positive affective states (Cohn et al., 1990; Field et al., 1990). When their children are toddlers or preschoolers, depressed mothers are, again, found to be more negative and/or less positive in interactions with their children (Kelley & Jennings, 2003; Lovejoy, 1991; Radke-Yarrow, Nottelmann, Belmont, & Welsh, 1993), and they engage in less effective control strategies (Kochanska, Kuczynski, Radke-Yarrow, & Welsh, 1987). To be noted is that not all research on mother-toddler interaction reveals such adverse effects of depression; and this is true even taking into account the type of depression and the mother's current depressive symptomatology (Frankel & Harmon, 1996). Depressed mothers continue to show more negative affect with school-age and adolescent children (D. Gordon et al., 1989; Hops

¹In the Brennan et al. (2002) study, fathers diagnosed with depression were more likely than well fathers to make hostile and critical statements about their children.

et al., 1987; Nolen-Hoeksema, Wolfson, Mumme, & Guskin, 1995; Tarullo, DeMulder, Martinez, & Radke-Yarrow, 1994). Trained observers judge them as being less accepting and exercising more psychological control than other mothers (e.g., extent to which parent controls child by inducing guilt, instilling anxiety, or withdrawing love; Garber & Flynn, 2001). Compared to well mothers, mothers diagnosed with depression have been found to be less engaged with the school-age daughters (Tarullo et al., 1994).

These findings on parent-child interaction were summarized recently in a meta-analysis of 46 observational studies of maternal depression and parenting behavior (Lovejoy, Graczyk, O'Hare, & Neuman, 2000). Parenting behaviors were categorized as negative if they involved negative affect or hostile or coercive behavior, disengaged if mothers ignored or withdrew from their child, or positive if they involved pleasant, enthusiastic interactions with the child. Compared to nondepressed mothers, depressed mothers had more negative, disengaged, and less positive interactions with their children. The difference between the depressed and nondepressed mothers was moderate in size for negative behavior ($d = .40$, 95% CI = .31 to .49), smaller in size for disengaged behavior ($d = .29$, 95% CI = .17 to .41), and small for positive behavior ($d = .16$, 95% CI = .08 to .23). These effects were similar regardless of whether depression was measured as a disorder or on a symptom scale.

Fathers versus Mothers

Although the evidence is sparse, the research comparing parenting behavior among depressed mothers and fathers indicates that fathering is less affected than mothering by depression. For example, Jacob and Johnson (1997) reported that depression in mothers was more strongly associated with parent-child negativity during a problem-solving task than was depression in fathers. Similarly, Field, Hossain, and Malphurs (1999) found that depressed fathers had higher-quality interactions (e.g., were more active, positive, and facially expressive, and displayed more game playing and higher-quality vocalizations) with their 3- to 6-month-old infants than did depressed mothers. These findings are consistent with meta-analytic results showing that depression in mothers was more closely related to children's internalizing (but not externalizing) problems than depression in fathers (Connell & Goodman, 2002). To be noted, however, are findings from one study showing that in families in which the father was depressed, positive communications by one family member were less often met with positive responses by other family members than in households in which neither parent or only mother was depressed (Jacob & Johnson, 2001).

The Family System

There is some evidence that one parent's depression may affect children's interactions with the nondisordered parent. For example, Jacob and Johnson (1997) reported that in families where one parent was depressed, affective expression was dampened across the entire family, including the communications between the child and the nondepressed parent. Among families of depressed women, Hops and colleagues (1987) observed a cycle in which depressed mothers' dysphoric affect made their husbands and children less aggressive, but family members' caring and aggressive affect also worked to dampen depressed mothers' dysphoric affect.

Timing, Severity, and Chronicity of Depression

Evidence emerging from some investigations suggests that the timing, severity, or chronicity of a mother's depression better predicts the quality of parent-child interaction than diagnostic status per se (Campbell et al., 1995; D. Gordon et al., 1989; Kochanska & Kuczynski, 1991; Kochanska, Kuczynski, et al., 1987; Langrock, Compas, Keller, Merchant, & Copeland, 2002; Tarullo et al., 1994; Timko, Cronkite, Berg, & Moos, 2002). In fact, in the aforementioned meta-analysis (Lovejoy et al., 2000), whether mothers were currently depressed when they were observed interacting with their children proved to be a stronger predictor of negative parenting behavior than was a history of depression. Although deficits in parenting may not persist after the mother's depression has remitted, differences between the children of depressed and well mothers may still be detected (Billings & Moos, 1986), possibly as a result of difficulties in the parent-child relationship that arose when the mother was still depressed (Murray et al., 1999).

The Role of Social Stressors

Depressed parents experience a range of social stressors, including marital difficulties, financial problems, and low social support (Hammen, 2002). Social stressors have been shown to exacerbate (i.e., moderate) the effects of depression on parenting (Stein et al., 1991) as well as to mediate the effects of depression on parent-child interaction; that is, mothers diagnosed with depression experience more social stressors, which, in turn, are associated with suboptimal parenting practices (D. Gordon et al., 1989; Hamilton et al., 1993; Teti et al., 1990). Other research indicates, however, that even though mothers diagnosed with depression report elevated levels of life stressors, negative attitudes about their children, dissatisfaction with themselves as parents, and unhappiness, they cannot be distinguished from well mothers during interactions with their children (Frankel &

Harmon, 1996). This apparent inconsistency may be explained by the possibility that differences between depressed and well mothers emerge only when well mothers are free from significant social adversity (Murray et al., 1996).

The offspring of depressed parents are at risk for a range of problem behaviors and, in some cases, children's problem behaviors may themselves act as social stressors that elicit negative reactions from parents, particularly when parents are already vulnerable to depression. Feske and colleagues (2001) provided evidence consistent with this argument, as they found that mothers reported more stressful life events than nonmothers following the onset of a depressive episode because they experienced child-related stressors. Another study of affectively ill, medically ill, and control mothers found that not only did mothers' symptom severity and negativity increase the risk of children's problem behaviors and low self-esteem, but that children's problem behaviors and low self-esteem predicted mothers' symptom severity and negativity in a reciprocal fashion (Hammen, Burge, & Stansbury, 1990).

A Note on Bipolar Depression

Comparison of mothers diagnosed with Bipolar and Major (i.e., unipolar) Depression to well mothers indicates that the parenting of the former group appears more compromised than that of the latter (Radke-Yarrow, 1998). More specifically, mothers diagnosed with Bipolar Disorder tend to make more negative judgments about and show more overall negative affect with their young children (Inoff-Germain, Nottelmann, & Radke-Yarrow, 1992); display more sad and anxious affect with their young daughters (Radke-Yarrow et al., 1993); prove less successful in managing their toddlers' behavior, particularly when their symptomatology is severe (Kochanska, Kuczynski, et al., 1987); prove less successful in engaging their preadolescents' attention (Tarullo et al., 1994); and are more likely to attribute their children's behavioral development to uncontrollable life events (Kochanska, Radke-Yarrow, et al., 1987). However, mothers diagnosed with bipolar and unipolar depression cannot be distinguished in terms of the negative affect they show in interactions with their toddlers (Radke-Yarrow et al., 1993), nor do they differ in terms of the strategies they use to control their children's behavior (Kochanska, Kuczynski, et al., 1987).

Alcohol Use Disorders

At least two kinds of alcohol use disorders need to be distinguished, though they are not always in investigations of parenting. Alcohol dependence is characterized by compulsive

drinking as well as tolerance to alcohol and symptoms of withdrawal following reduction of alcohol intake. Alcohol abuse is a maladaptive pattern of substance use manifested by recurrent and significant adverse consequences related to persistent alcohol use (American Psychiatric Association, 2000). Lifetime prevalence rates of alcohol dependence range from 8% to 14%, whereas prevalence rates of alcohol abuse have been estimated as 5% in community and national probability surveys (American Psychiatric Association, 2000). Alcohol abuse and dependence are more common in males than females (ratios as high as 5:1), although the sex ratio depends on the age group, with females starting to drink heavily later in life than males. The studies reviewed here typically include individuals who meet criteria for either alcohol dependence or abuse (or both).

Because of gender differences in the prevalence of alcohol use disorders, fathers rather than mothers tend to be the focus of studies on how alcohol use affects parenting, reversing the trend in the parenting literature more generally. Research on alcoholic fathers largely involves observations of families of alcoholics interacting in lab settings or in the home. These studies consistently find that when interacting with their children, alcoholic fathers tend to show higher levels of negativity (Ammerman, Loeber, Kolko, & Blackson, 1994; Moser & Jacob, 1997), lower levels of positivity and congeniality (Jacob, Krahn, & Leonard, 1991), lower levels of problem solving (Jacob et al., 1991) and ability to keep children on task (Whipple, Fitzgerald, & Zucker, 1995), less synchronicity (Whipple et al., 1995), and, with infants, less sensitivity and verbalization (Eiden, Chaves, & Leonard, 1999), thereby fostering insecure infant-father attachment bonds (Eiden, Edwards, & Leonard, 2002). Studies of children of alcoholics find that a family history of alcoholism is associated with a lack of emotional warmth in parents (Barnow, Schuckit, Lucht, John, & Freyberger, 2002), more parent-child conflict and physical and emotional abuse (Reich, Earls, & Powell, 1988), and lower levels of monitoring and disciplinary consistency (Chassin, Pillow, Curran, Molina, & Barrera, 1993), although such difference are not detected in each and every investigation (Callan & Jackson, 1986). The focus in this literature on maritally intact families of alcoholics obscures the fact that, as with antisocial behavior, many alcohol- and substance-abusing fathers are absent from the household in which their children grow up (McMahon et al., 2002).

Far more has been written about drug-abusing than alcohol-abusing mothers (Mayes, 1995). Nevertheless, the small research base suggests that alcoholism is more strongly linked to parenting problems among mothers than fathers. For example, Moser and Jacob (1997) observed parent-child interactions in families where only the mother,

only the father, both parents, or neither parent was alcoholic. Alcoholic fathers were indistinguishable from control fathers unless both parents were alcoholics, in which case fathers had more negative and less positive interactions with their children relative to any other fathers. In contrast, mother-child interactions were characterized by high levels of negativity regardless of whether only the mother or both parents were alcoholics. Consistent with these findings are recent meta-analytic results showing that mothers' alcoholism and substance use disorders were more strongly linked to children's externalizing problems than were fathers' substance use disorders or alcoholism (Connell & Goodman, 2002).

As noted earlier in the case of depression, alcoholism in one parent has been associated with suboptimal parent-child interactions involving the nondisordered parent (Chassin et al., 1993; Haber, Leonard, & Rushe, 2000). However, the effects of one parent's drinking on the other's parenting behavior may depend on factors such as the quality of their relationship or the level of psychopathology in the other parent (Eiden & Leonard, 1996). Currently, there is very little evidence that a mother's behavior buffers her children from the effects of a father's alcoholism (Curran & Chassin, 1996).

Child Maltreatment

Several investigations reveal an association between parental alcohol abuse and child maltreatment (Widom & Hiller-Sturmhofel, 2001). A 1991 national survey found that 24% of substantiated reports of maltreatment involved a caretaker who abused alcohol (Magura & Laudet, 1996). The proportion of maltreating parents who abuse alcohol is even higher (31%) among families where maltreatment is deemed sufficiently serious to require the removal of the child into care (Murphy et al., 1991). The association between alcohol abuse and child maltreatment appears strongest when alcoholism is comorbid with other drug problems (Murphy et al., 1991). Moreover, although alcohol problems characterize a substantial proportion of parents who mistreat their children, there is little evidence that parents who abuse alcohol are at elevated risk of child maltreatment, with existing studies relying on retrospective reports of parental alcoholism and child abuse (Harter & Taylor, 2000; Miller, Maguin, & Downs, 1997).

Comorbidity and Causality

Alcohol disorder is highly comorbid with other mental disorders (Regier et al., 1990). Thus, when a parent is an alcoholic, it is not always clear whether suboptimal parenting is a function of alcoholism or comorbid psychopathology. Several researchers have attempted to delineate the unique ef-

fects of alcohol disorder on parenting practices (Chassin et al., 1993), but results have been inconsistent, with some reporting that high and low antisocial fathers could be distinguished in interactions with their wife and children (Haber et al., 2000) and others finding that antisocial behavior neither mediated nor moderated the effects of alcohol problems on parent-child interactions (Eiden et al., 1999; Moss, Lynch, Hardie, & Baron, 2002). However, Eiden and colleagues did find that alcoholic fathers interacted less sensitively with their infants because of their depressive symptomatology.

Given the reliance on correlational data in studies of alcohol use and parenting, most researchers have been unable to conclude that the effects of alcohol use on parenting are truly causal. Although the ethics of conducting experimental research on alcohol use and parenting have been questioned, some investigators have manipulated alcohol intoxication to illuminate its effects on parenting. Lang, Pelham, Atkeson, and Murphy (1999) developed an experimental paradigm in which sober parents and parents who were intoxicated as part of the experiment engaged in a problem-solving task with control children and with confederates who were trained to behave like children with Conduct Disorder or Attention-Deficit/Hyperactivity Disorder. Compared to parents who were sober, intoxicated parents were less attentive and engaged in more irrelevant talk while failing to sustain task-oriented work behaviors. Reflecting an inconsistent parenting style, they issued more commands while at the same time engaging in more indulgent behaviors. Moreover, intoxicated parents were less likely than sober parents to perceive the confederate's behavior as deviant. Lang and colleagues (1999) noted that attention and perception problems might mediate the association between parents' drinking and children's conduct problems. In a study in which alcoholic beverages were made available to participants, fathers (regardless of diagnostic status) were more negative during family problem-solving interactions if they were in the drink versus the no-drink condition (Jacob et al., 1991). Results of this work clearly suggest that although some of the impact of alcohol use disorder on mothering and fathering might be an artifact of other factors, this is unlikely to be the case entirely.

Antisocial Personality Disorder

According to *DSM-IV* (American Psychiatric Association, 2000), Antisocial Personality Disorder (ASPD) is characterized by a pervasive pattern of disregard for, and violation of, the rights of others that begins in childhood or early adolescence and continues into adulthood. ASPD is

more common in men than women, with prevalence rates of about 3% among men and 1% among women in community samples (American Psychiatric Association, 2000). Given the dearth of research on diagnosed ASPD, this summary includes studies of parenting behavior and serious delinquency or criminality.

As with alcohol use disorder, research on parenting and ASPD focuses more heavily on fathers than mothers. Although young men who engage in high levels of antisocial behavior compose a small percentage of the population, they father a disproportionate number of children (Wei, Loeber, & Stouthamer-Loeber, 2002). Despite this, they are less likely than other fathers to see their children every day (because a considerable proportion are incarcerated), to be involved in their children's care, or to support their children financially (Jaffee, Moffitt, Caspi, & Taylor, 2003; Wei et al., 2002).

When fathers who have a history of antisocial behavior are involved with their children, the quality of their parenting may be compromised. Observing young fathers interacting with their toddlers during a puzzle-solving task, Fagot, Pears, Capaldi, Crosby, and Leve (1998) found that those who had a history of antisocial behavior more often told their children what to do (rather than offer strategies for solving the task) and provided them with more negative feedback compared to control fathers. Verlaan and Schwartzman (2002) reported that fathers who had a history of antisocial behavior reported using more hostile, rejecting behaviors with their sons, who, in turn, had more externalizing problems. Shears, Robinson, and Emde (2002) reported that in a sample of 87 low-income fathers, men with a history of antisocial behavior reported low ratings of themselves as fathers and were less involved with their children, although they did not report being less emotionally attached to their child.

Turning to the case of mothering and ASPD, the first thing to be noted is that girls who have a history of Conduct Disorder are disproportionately likely to become teen mothers (Bardone, Moffitt, Caspi, & Dickson, 1996; Jaffee, 2002; Kovacs, Krol, & Voti, 1994; Zoccolillo, Meyers, & Assister, 1997), and at least one study has shown that, among adolescent mothers, those who had more symptoms of antisocial behavior were less responsive with their infants, though not more controlling or less sensitive (Casidy, Zoccolillo, & Hughes, 1996). These findings were echoed in study of 141 low-income women who were categorized into antisocial, clinical (e.g., depressed), or non-clinical groups based on their scores on the Antisocial Practices content scale of the Minnesota Multiphasic Personality Inventory 2 (J. N. Butcher, Dahlstrom, Graham,

Tellegen, & Kaemmer, 1989; see also Bosquet & Egeland, 2000). Observed during interactions with their 13- and 24-month-old infants, the clinical and nonclinical mothers were virtually indistinguishable. However, mothers in the antisocial group were less understanding of their children and more coercive, harsh, hostile, and abusive, although they did not differ from the nonantisocial groups in terms of more positive behaviors with their children.

A number of studies have shown that mothers who have a history of antisocial behavior are more likely to use ineffective disciplinary practices with their school-age children (Bank, Forgatch, Patterson, & Fetrow, 1993; Capaldi & Patterson, 1991; Simons, Beaman, Conger, & Chao, 1993a; Verlaan & Schwartzman, 2002). Simons and colleagues reported that individual characteristics of the mothers, such as their history of antisocial behavior, better accounted for variation in disciplinary effectiveness than did social stressors and supports (e.g., economic pressures, negative life events, and social supports). However, this study also showed that antisocial behavior and social stressors were closely related. For example, mothers who had a history of antisocial behavior reported more economic pressures and negative life events. They also reported more psychological distress, partly because of the negative life events they experienced. These factors, in turn, predicted ineffective discipline. Similarly, Capaldi and Patterson found that mothers who had a history of antisocial behavior were less skillful parents (which, in turn, was related to their boys' adjustment) and were also the parents whose relationships were the least stable.

Finally, a large research literature shows that parents who have a history of ASPD are at increased risk of abusing their children (Brown, Cohen, Johnson, & Salzinger, 1998; DeBellis et al., 2001; Dinwiddie & Bucholz, 1993; Moffitt, Caspi, Harrington, & Milne, 2002; Walsh, McMillan, & Jamieson, 2002). Moreover, mothers with a history of Conduct Disorder may be at increased risk of having their children removed into care (for review, see Pajer, 1998).

Schizophrenia

Schizophrenia is characterized by positive symptoms that reflect an excess or distortion of normal function (e.g., delusions, hallucinations, disorganized speech) and negative symptoms that include restrictions in the range and intensity of emotional expression, in the fluency and productivity of thought and speech, and in the initiation of goal-directed behavior (American Psychiatric Association, 2000). The lifetime prevalence of Schizophrenia is estimated at 0.5% to 1.0%. Schizophrenia is somewhat more common in men

than women, although the sex ratio varies depending on diagnostic criteria and age of onset (Castle, 2000).

In clinic samples, the majority (59%) of women with nonaffective psychotic disorders are mothers (Hearle & McGrath, 2000). Although men with Schizophrenia are less likely than other men to have children (Jablensky, 1995), a study of psychiatric outpatients (most of whom had diagnoses of Schizophrenia) found that 51% had fathered children, although fewer than a third were being raised by their father and mother together (Coverdale, Schotte, Ruiz, Pharies, & Bayer, 1994). The lowered fertility rate coupled with the lack of paternal involvement among men with diagnoses of Schizophrenia may account for the dearth of evidence about their parenting practices.

As reviewed by Mowbray, Oyserman, Zemencuk, and Ross (1995), the majority of studies about parenting and Schizophrenia involve observations of mother-infant dyads admitted to psychiatric hospital mother-and-baby units (MBU). These inquiries involve small clinic samples, thus compromising the generalizability to the population of psychiatrically ill mothers; relatively short-term follow-ups of parents' behavior; and often lack nonpsychiatric control groups that would provide information about the degree to which the parenting of mothers diagnosed with Schizophrenia was impaired relative to that of well mothers. Nevertheless, clinic studies are generally consistent in showing that, compared to well mothers, mothers diagnosed with Schizophrenia are less sensitive and responsive with their infants and have difficulty matching their infants' affect or behavior (Cohler, Gallant, Grunebaum, Weiss, & Gamer, 1980; McNeil, Naslund, Persson-Blennow, & Kaij, 1985; Naslund, Persson-Blennow, & McNeil, 1985; Persson-Blennow, Naslund, & McNeil, 1984). In very rare cases, a parent who is experiencing a psychosis will threaten a child's life, but these instances of "terrorizing attacks" on children are uncommon (Anthony, 1986). One study found that the quality of parent-child interactions was related to changes in mothers' positive symptoms (e.g., thought disorder, paranoia) but not negative symptoms, possibly because negative symptoms showed relatively little improvement over the course of treatment. At discharge, mothers whose negative symptoms were more prominent were inattentive, unresponsive, understimulating, and disorganized in interactions with their infants (Snellen, Mack, & Trauer, 1999).

Results of at least three studies indicate that the quality of mother-child interactions is poorer among dyads where the mother has Schizophrenia compared to dyads where the mother is diagnosed with depressive disorder. Compared to mothers with depression, mothers diagnosed with Schizophrenia are less responsive and sensitive, more demanding

and intrusive, less stimulating, more withdrawn, and provide a poorer quality physical environment (S. H. Goodman & Brumley, 1990; Hipwell & Kumar, 1996; Riordan, Appleby, & Faragher, 1999). In their observations of unipolar depressed, bipolar depressed, and schizophrenic mothers on an MBU, Hipwell and Kumar reported that, at discharge, over 75% of the mothers diagnosed with unipolar or bipolar depression had scores in the normal range on a mother-child interaction scale, whereas this was true of only 33% of the mothers diagnosed with Schizophrenia. Although the majority of mothers diagnosed with unipolar or bipolar depression were discharged home together with their child from the MBU with no recommended formal supervision, most mothers diagnosed with Schizophrenia were not so discharged.

As the Hipwell and Kumar (1996) research suggests, a major issue for mothers with Schizophrenia is the possibility that their children will be removed from their care. In a study of 58 mothers who had been hospitalized for severe mental illness (predominantly Schizophrenia), 68% had a child from whom they had been permanently separated by the time the child was 18 years of age (Dipple, Smith, Andrews, & Evans, 2002). In half the cases, separation occurred during the mother's first episode of illness and, following separation, 66% of the children had no further contact with their mother; 20% had only sporadic contact for the remainder of their childhood. Reasons for separation included concern by the authorities that the mother was providing inadequate care (physical and emotional abuse and neglect were common), a breakdown in the mother's relationship with the father, and a history of prolonged periods of hospitalization (Dipple et al., 2002).

Finally, some researchers have noted that poverty and lack of social supports often co-occur with severe mental illness, and they theorize that severe mental illness may affect parenting not only directly, but also indirectly, by increasing family stress and depleting family support systems (Oyserman, Bybee, Mowbray, & MacFarlane, 2002). In one of the few population studies of mothers with a serious mental illness (Schizophrenia, unipolar or bipolar depression), Oyserman and colleagues found that mothers whose first episode of disorder occurred at an early age had fewer social supports and were less involved in their children's schooling. Mothers whose current mental health and functioning was poor reported more social and material stressors, which were, in turn, associated with less positive parenting attitudes. Only the number of hospitalizations (per year of mental illness) had a direct effect on parenting: Mothers who reported more hospitalizations had more positive parenting attitudes, leading the authors to propose that hospitalization

stabilized these mothers or increased the value they placed on motherhood. Consistent with these findings, Rogosch, Mowbray, and Bogat (1992) showed that among a sample of mothers diagnosed primarily with Schizophrenia, those who experienced more emotional support and had less frequent relapses reported more authoritative parenting attitudes.

Conclusion

Despite very different symptom presentations, there appears to be little specificity in the association between different mental disorders and parenting practices. High levels of comorbidity among disorders and the frequent co-occurrence of social stressors with psychiatric illness may account for the finding that most disorders are associated with a pattern of parenting characterized by less sensitive, less responsive, and contingent caregiving. Although some studies of psychiatric disorder and parenting practices report data from community samples, much of the research in this area still relies on clinic samples and samples of convenience, particularly the literature on parenting practices among parents diagnosed with alcoholism and Schizophrenia. Moreover, although a growing number of studies have shown that suboptimal parenting practices both mediate and moderate the association between parent and offspring psychopathology, more research is needed to explore bidirectional effects of parent and offspring disorder on parenting and to illuminate the circumstances under which parenting is not impaired. Finally, given the heritable nature of these disorders, genetically sensitive designs are needed to determine whether suboptimal parenting accounts for the association between parent and offspring psychopathology, even controlling for children's genetic risk for disorder.

PERSONALITY

Despite early interest by psychoanalytically oriented investigators in parental personality characteristics and their effects on parenting behavior, the study of these issues was interrupted by important shifts in the field of personality psychology during the 1970s and into the 1980s (for reviews, see Baumeister, 1999; Caspi, 1998; McAdams, 1997; Winter & Barenbaum, 1999). A major contribution to the reemergence of personality as an important area of inquiry came from the acknowledgment and embrace of the Big Five factor model of personality, which did much to organize a rather disparate area of inquiry. The Big Five factors—neuroticism, extraversion, openness to experience,

agreeableness, and conscientiousness—were identified first by Tupes and Christal (1961), who found through factor-analytic techniques that long lists of personality variables compiled by Cattell (1943, 1945) could be reduced to five broad-band personality factors. This five-factor structure has since been replicated in diverse samples and across numerous raters, such as self-reports, peers, and clinicians (John & Srivastava, 1999). In this chapter, we organize discussion of personality and parenting around these core dimensions of personality before proceeding in a final subsection to consider psychological mechanisms that may account for how personality comes to be related to parenting (see Belsky & Barends, 2002). Once again, it is important not to lose sight of the very real possibility that linkages detected to date between personality and parenting are genetically mediated. Having said that, attention should be directed to Spinath and O'Connor's (2003, p. 786) recently reported study of 300 pairs of adult twins (from Germany) showing that "the moderate phenotypic covariation between personality and parenting was attributed largely to nongenetic factors."

Neuroticism

Neuroticism reflects adjustment versus emotional instability, and measures of neuroticism identify individuals prone to psychological distress, unrealistic ideas, excessive cravings or urges, and maladaptive coping responses. A person scoring high on this trait worries a lot; is nervous; emotional, and insecure; and feels inadequate, whereas a person scoring low is calm, relaxed, unemotional, hardy, secure, and self-satisfied. Because factor-analytic studies indicate that indices of the negative emotions of anxiety, hostility, and depression all load on a single factor (Costa & McCrae, 1992), whether measured as states or traits, some prefer to use the term negative affectivity rather than neuroticism (Tellegen, Watson, & Clark, 1999; Watson & Clark, 1984).

The important point is less what this trait is called than what this trait reflects. And the fact that it reflects the proclivity or disposition to experience anxiety and hostility as well as depression raises important questions about the plethora of work carried out on depression and mothering in the field of developmental psychology over the past 2 decades. In point of fact, one is forced to wonder whether studies in which only depression is measured actually present evidence pertaining only to depression and mothering or, instead, negative affectivity more generally, including anxiety and hostility. Until these other negative emotion facets of neuroticism are examined in studies (of normal

samples) that also include measures of depression (for a singular good example, see Leinonen, Solantaus, & Punamäki, 2003), it will be impossible to address this issue.

The fact that the empirical literature is the way it is means that much of the work to be considered in this section deals with depression. But because the effect of psychopathology on parenting has already been considered, we restrict ourselves here to research dealing with depression measured as a continuous variable in nonclinical samples. We begin with investigations focused on parents of infants and then proceed developmentally from that point forward. The reader will note a great deal of consistency between findings from studies reviewed previously dealing with clinical samples and the work considered here focused on nonclinical samples.

During the infancy period, maternal depression has been the facet of neuroticism that has received the most empirical attention. Although the evidence is not without some inconsistency, there is repeated indication, even in nonclinical samples, that when mothers experience more versus fewer symptoms of depression, they provide less sensitive care to their infants. This result emerged in the work of the NICHD Early Child Care Research Network (1999), in which depression was repeatedly measured in a sample of more than 1,000 mothers, as was maternal sensitivity, across the first 3 years of the child's life. Relatedly, Crockenberg (1987b) reported in a study of teenage mothers that those experiencing more psychological distress engaged in more simple custodial and unstimulating care of their infants than other mothers. And when Zaslow, Pederesen, Cain, Suwalsky, and Kramer (1985) examined relations between mothers' feeling "blue" on 8 or more days since the birth of their 4-month-old children and maternal behavior, they observed that increased depression predicted less smiling at, less speaking with, and less touching of the infant. In addition to undermining active involvement with the infant, negative affectivity may also promote negative and intrusive maternal behavior, as Diener and colleagues (Diener, Mangelsdorf, Contreras, Hazelwood, & Rhodes, 1995; Goldstein, Diener, & Mangelsdorf, 1996) discovered on observing adolescent Latino mothers with their 3- to 24-month-olds.

During the preschool and middle childhood years, similar results were obtained. In one investigation of rural African American and European American families, for example, high levels of emotional distress (i.e., anxiety, depression, irritability) among mothers were related to low levels of positive parenting (e.g., hugs, praise) and high levels of negative parenting (e.g., threats, slaps, derogatory statements) and also strong endorsement of authoritarian child-rearing

values during the course of structured parent-child interactions (Conger, McCarty, Yang, Lakey, & Kropp, 1984). In more recent research, Kanoy, Ulku-Steiner, Cox, and Burchinal (2003) found that higher levels of hostility, one facet of neuroticism, measured during pregnancy predicted high levels of physical punishment when children were 2 and 5 years of age in the case of both mothers and fathers. In other recent work, Kochanska, Aksan, and Nichols (2003) found that mothers scoring higher on neuroticism engaged in more power-assertive parenting when interacting with their 14- to 54-month-old children in a laboratory setting designed to evoke parental discipline. When Zelkowitz (1982) studied poor African American and European American mothers of 5- to 7-year-olds, she further observed that high levels of anxiety and depression predicted high expectations for immediate compliance on the part of the child, but inconsistency in following up such demands when the child did not comply. Furthermore, high levels of psychological distress were associated with more hostile and dominating behavior, less reliance on reasoning and loss of privileges when disciplining the child, and more intensive demands for the child's involvement in household maintenance (Longfellow, Zelkowitz, & Saunders, 1982).

During the teenage years, neuroticism or negative affectivity continues to be associated with problematic parenting. For example, Gondoli and Silverberg (1997) reported that mothers who experienced emotional distress (i.e., depression, anxiety, low self-efficacy) were less accepting of their teen's behavior during problem-solving discussions and were less supportive of the child's psychological autonomy than other mothers. In an analysis of almost 1,000 mothers and fathers of 10- to 17-year-olds interviewed as part of a national survey, Voydanoff and Donnelly (1988) found that feeling sad, blue, tense, tired, and overwhelmed was related to parents not participating in activities with their children, though such negative affectivity proved unrelated to parental monitoring. In a series of researches, Conger and associates (1992, 1993; Conger, Patterson, & Ge, 1995; Simons et al., 1993a) studied family interaction patterns in a large sample of Iowa farm families and discerned both direct and indirect effects of negative affectivity on maternal and paternal behavior. Not only did depression predict more harsh and inconsistent discipline on the part of both mothers and fathers (Conger et al., 1995; Simons, Beaman, Conger, & Chao, 1993b) and less nurturant behavior by both parents when interacting with sons (Conger et al., 1992), though not daughters (Conger et al., 1993), but in the case of both mothers and fathers with sons and daughters, elevated levels of depression predicted increased marital conflict and, thereby, lower levels

of nurturant parenting (Conger et al., 1992, 1993). Such indirect pathways of influence of parents' general psychological functioning on their parenting are consistent with Belsky's (1984) process model of the determinants of parenting. Finally, Brody, Murry, Kim, and Brown (2002) have recently shown that higher levels of depression (in concert with lower levels of optimism and self-esteem) predict less involved/vigilant parenting and lower quality mother-teen discussions in their short-term longitudinal study of 150 African American families living in single-parent families in the rural South.

In sum, whether one considers research on infants, toddlers, preschoolers, school-age children, or adolescents, there is repeated indication that high levels of depression, even in nonclinical samples, and of other facets of neuroticism, including anxiety and irritability/hostility, are related to less competent parenting. This effect can take the form of less active and involved parenting, as well as more negative, intrusive, and overcontrolling parenting.

Extraversion

Extraversion reflects the quantity and intensity of interpersonal interaction, activity level, need for stimulation, and capacity for joy that characterize individuals. A person scoring high on extraversion is considered sociable, active, talkative, person-oriented, optimistic, fun-loving, and affectionate, whereas a low-scoring individual is reserved, sober, unexuberant, aloof, task-oriented, retiring, and quiet. One might anticipate, on the basis of this description, that extraverted individuals might function better as parents than less extraverted parents, if only because parenting is a social task involving another, though dependent, person. On the other hand, one might imagine that high levels of extraversion and especially of sociability might predispose one to be more interested in more social exchange than might be experienced by a parent, particularly one who remains home all day with children.

Although the database is by no means extensive, in general the evidence is supportive of the first prediction, namely, that of a positive association between extraversion and sensitive, responsive, emotionally engaged, and stimulating parenting. True virtually to the definition of extraversion, Levy-Shiff and Israelashvili (1988) found that Israeli men scoring high on this construct manifested more positive affect and engaged in more toy play and teaching when interacting with their 9-month-olds in their homes than men scoring low on extraversion. Mangelsdorf and her colleagues (1990) detected similar personality-parenting associations when studying mothers of 9-month-olds. And

Belsky, Crnic, and Woodworth (1995) essentially replicated both sets of results during the course of naturalistic home observations with mothers, fathers, and their 15- and 21-month-old toddlers. These investigators reported that mothers and fathers alike who were more extraverted expressed more positive affect toward their children and were more sensitive and cognitively stimulating when observed at home late in the afternoon and early in the evening. Finally, in a study of mothers, fathers, and their children up to 8 years of age, more extraverted parents reported engaging in more positive supportive parenting, such as displaying positive affection and encouraging independence (Losoya et al., 1997). Apparently, the link between extraversion and positive parenting is not restricted to the infant-toddler period. To date, however, there are no studies linking this personality trait with parenting during the adolescent years.

Agreeableness

Agreeableness reflects one's interpersonal orientation along a continuum from compassion to antagonism in thoughts, feelings, and actions. A person scoring high on this trait is soft-hearted, good-natured, trusting, helpful, forgiving, gullible, and straightforward, whereas a person scoring low is cynical, rude, suspicious, uncooperative, vengeful, ruthless, irritable, and manipulative. Clearly, the basic prediction regarding parenting would be that more agreeable individuals would make better parents, at least from the child's perspective. As it turns out, only a handful of studies have examined the relation between this particular personality trait and parenting, three of which have just been mentioned and one of which failed to chronicle any linkage between agreeableness and parenting reported by a large sample of German parents (Spinath & O'Connor, 2003). In the aforementioned toddler work by Belsky et al. (1995), higher levels of agreeableness predicted greater maternal (but not paternal) positive affect and sensitivity and lower levels of negative affect and intrusive-overcontrolling behavior. In more recent research with toddlers and preschoolers, Kochanska et al. (2003) found that mothers scoring higher on agreeableness engaged in less power-assertive discipline when observed in a series of structured laboratory situations. Consistent with these findings, Losoya et al. (1997) found in their study of parents with children as old as 8 that agreeableness was positively associated with supportive parenting and negatively associated with negatively controlling parenting. Kochanska, Clark, and Goldman (1997) reported that lower levels of agreeableness were related to more power-assertive and less

responsive parenting in their study of young children, although in other research by this team, only the agreeableness-responsiveness association was replicated (L. A. Clark et al., 2000). Clearly, the evidence just reviewed is rather consistent with the hypothesis originally advanced.

Openness to Experience

The person who is open to experience tends to enjoy new experiences, have broad interests, and be very imaginative; in contrast, a person scoring low on this trait is down-to-earth, practical, traditional, and pretty much set in his or her ways. Predictions from this trait to parenting are less straightforward than was the case with respect to the other Big Five traits considered to this point. Only three investigations have explored this topic, with one showing that Israeli fathers who were more open to experience engaged in more basic caregiving of their infants than fathers less open to experience (Levy-Shiff & Isarelashvilli, 1988), perhaps because the father role itself is a new experience worth exploring for these highly open men. The other study found that openness was positively related to positive parenting for mothers and fathers alike (Losoya et al., 1997). Finally, Spinath and O'Connor (2003, p. 803) found that German parents who were less open to experience engaged in more overprotective parenting, a result they explained by speculating that "individuals who are themselves not open to experiences" tend to "restrict the behaviors or intrude on the activities of their children."

Conscientiousness

Conscientiousness reflects the extent to which a person is well-organized and has high standards, always striving to achieve his or her goals. Thus, a person who scores low on conscientiousness is easygoing, not very well organized, tending toward carelessness, and preferring not to make plans. Once again, it is not exactly clear how this trait should relate to parental behavior, as it seems eminently possible that, however attractive high conscientious may appear, especially to an employer, it could prove too demanding to a child. At the same time, disorder and chaos, in contrast to organization, are typically not in children's best interests, so one could imagine low levels of conscientiousness also predicting parental behavior that might not be especially supportive of children's functioning. The study by Losoya et al. (1997) that examined this trait in relation to the child-rearing attitudes and practices of mothers and fathers with children under 8 years of age found conscientiousness to be positively related to supportive parenting

and negatively related to negative, controlling parenting. L. A. Clark and associates (2000) chronicled a similar relationship when looking at mothers of toddlers, finding that more conscientious mothers are more responsive and less power-assertive than less conscientious mothers. Although results of these two studies begin to suggest that conscientiousness and positive parenting go together, it should be noted that one German study failed to chronicle any significant linkage between this dimension of personality and four reliable, self-report measures of parenting (Spinath & O'Connor, 2003).

Processes Linking Personality and Parenting

This summary of research on personality and parenting makes it clear that if one had to choose a parent to provide care for oneself, one's development would likely benefit from choosing a parent who is low in neuroticism, high in extraversion and agreeableness, and perhaps high in openness to experience and conscientiousness. This is because these kinds of individuals have been repeatedly found to provide care that is more supportive, sensitive, responsive, and intellectually stimulating, almost irrespective of the child's age, though it must be acknowledged that, with the exception perhaps of recent work on negative affectivity (i.e., neuroticism), most research on the role of personality in shaping parenting has been carried out on parents of younger rather than older children. It is encouraging, nevertheless, that in the time since Belsky (1984) advanced his model of the determinants of parenting there is so much research to report on fathering.

It is one thing to observe, as we have, that a parent's personality is predictive of his or her parenting, and quite another to understand the mechanisms responsible for this relationship. Two possibilities that have received some limited attention in the literature deserve more attention in the future. The first involves attributions; the second, mood and emotion.

There is increasing appreciation in developmental research that attributions play an important role in close relationship processes, including in the parent-child relationship. More specifically, models of social cognition that have been advanced in the marital, developmental, and social psychology literatures (e.g., Bradbury & Fincham, 1990; Dix, Ruble, & Zamarano, 1989; Dodge, 1986) have been applied to the study of parenting (e.g., Bugental & Happaney, 2002; Bugental & Shennum, 1984). For example, it has been shown that parents who think their child is whining because he or she is tired are inclined to respond to the child in a manner quite different (i.e., sensi-

tive) from when they believe the child is trying to manipulate them. Thus, Bugental and Shennum were able to show that mothers with more dysfunctional attributional styles responded to children in ways that maintained or enhanced the child's difficult behavior, a finding that was experimentally reproduced by Slep and O'Leary (1988) by manipulating parental attributions in a challenging situation. Relatedly, Johnston and Patenaude (1994) found that parents were more likely to regard oppositional-defiant child behavior as under the child's control than inattentive-over-reactive behavior, and this accounted for why the former evoked more negative parental reactions than the latter.

The fact that such attributions predict much the same parenting behavior that personality characteristics predict raises the possibility that one means by which personality shapes parenting is via attributions. Is it the case, as seems likely, for example, that it is neurotic rather than agreeable parents who are most likely to attribute negative intent to their young children when they misbehave? And if so, does this dynamic account for why these personality traits predict parenting in the ways that they do?

Because attributions themselves are linked to emotion, it is reasonable to wonder further about the role that emotion plays in mediating the effect of personality on parenting. After all, in the aforementioned experimental study by Slep and O'Leary (1998), the manipulation of mothers' attributions affected the degree to which they felt angry with their children. Emotion, of course, is central to the personality traits of neuroticism, also labeled negative affectivity, and extraversion, sometimes referred to in terms of positive affectivity.

Two studies to date have examined the mediating role of emotion in accounting for personality-parenting relations. In a German investigation of almost 300 families with 8- to 14-year-old sons, Engfer and Schneewind (1982) showed, via path analysis, that maternal irritability and nervousness (i.e., neuroticism) promoted the harsh punishment of their children via mother's proneness to anger. Belsky et al. (1995) tested and found some support for an "affect-specific" process whereby personality affects mood and, thereby, parenting, in their home-observational study of families rearing 15- and 21-month old sons: Whereas extraversion with its emphasis on the experience of positive emotions predicted mothers' expressions of positive but not negative affect toward their toddlers, neuroticism with its emphasis on the experience of negative emotions predicted mothers' expressions of negative but not positive affect. In light of these results and those concerning attributions, it seems appropriate to encourage further work examining the mediating role of attributions and emo-

tion in accounting for some personality-parenting linkages, including the proposition that personality → emotion → attribution → parenting.

THE MARITAL/PARTNER RELATIONSHIP

A well-acknowledged fact, dating back as far as the 1930s, about the marital relationship and child psychopathology is that antisocial, aggressive, or otherwise problematical child behavior is found disproportionately in children growing up in families in which marital/partner relations are distressed and/or highly conflicted (Cummings & Davies, 2002; Emery, 1989; Fincham, 2003; Grych, 2002). Indeed, growing up in a high-conflict family or one in which discord and disharmony characterize the spousal relationship is known to be associated with externalizing disorders, including excessive aggression, unacceptable conduct, vandalism, noncompliance, and delinquency; dysfunctional social skills and relationships with peers and adults; as well as diminished academic performance, manifested by poor school grades and teachers' reports of problems in intellectual achievement and abilities (Cummings & Davies, 1994; Depner, Leino, & Chun, 1992; Reid & Crisafulli, 1990). In all likelihood, some of this association between troubled marital/partner relations and problematic child development is spurious, rather than causal, reflecting the correlated effects of heritable processes shared by parent(s) and child. Moreover, it is widely appreciated that some of the invariably causal contribution of marital distress to problematic child behavior is direct, emanating from children's exposure to conflict, especially unresolved, angry conflict (for review, see Cummings & Davies, 1994). Processes involving modeling and contagious emotion dysregulation have been posited to account for such direct effects of marriage on child functioning (Davies & Cummings, 1994; B. Wilson & Gottman, 2002). But it is also apparent that some of the association between distressed marriage and child dysfunction is mediated via parenting and parent-child relationship processes (Belsky, 1981, 1984; Elder, 1974; Engfer, 1988; Erel & Burman, 1995; Grych, 2002; Levendosky et al., 2003).

Belsky (1981) was among the first to draw attention to the need of developmentalists and clinicians to study marriage, parenting, and child development, pointing out that the scholarly investigation of these domains of inquiry was dispersed across distinctive and all too often unrelated literatures and even academic fields. Family sociologists, for example, paid a great deal of attention to marital quality, especially as it changed across the transition to parenthood

and the life course more generally, but had little to say (at the time) about parenting and child development. Clinical psychologists, in contrast, focused on marital distress and child behavior problems but paid limited attention (at the time) to parenting. And developmental psychologists, who studied parenting and child development, usually within the normal range of functioning, treated the adults in the family (at the time) as if their only social roles were that of parent, basically ignoring the marital relationship. Over the past 2 decades, the study of family processes and child development have changed dramatically, so what once were disciplinarily isolated areas of inquiry have become much more interrelated.

One of the major forces of change in the study of child development in the family was the recognized need, back in the 1970s, to pay more attention to the role of the father. Belsky (1981) noted, for example, that once the father was added to the more traditional study of mother-child relationships, the complexity of the family changed, with a need to focus not only on an additional parent-child relationship, but on the relationship between parents—the marriage—and one that often existed prior to the arrival of children. Early students of the father-infant relationship emphasized the fact that the influence of the father on child functioning might be primarily indirect and mediated by the wife in her capacity as mother (e.g., Parke, 1978; Pedersen, Yarrow, Anderson, & Cain, 1978). When examined from the perspective of today, it is clear that a number of viewpoints highlight the role and nature of the marriage in shaping parenting and parent-child relationships (Grych, 2002). These will be discussed in turn before turning to consider empirical findings from the literature. All, it should be noted, are consistent with Belsky's (1981, 1984) claim that the marital relationship was the first-order support system for parents, especially mothers, and thus likely to impact parenting behavior.

Processes and Perspectives on the Marriage-Parenting Relationship

As Grych (2002) has pointed out, most (explicit or implicit) models of parenting presume some kind of affective spillover from the marriage to the parent-child relationship, though they differ in terms of the processes involved. In this section, we consider several alternative, but not mutually exclusive, models of influence.

Affective Spillover and Withdrawal

The notion that linkages exist between the quality of the marriage and in the nature and/or quality of parenting be-

cause emotions experienced in one relationship spill over and affect the other relationship is a guiding assumption in marriage-parenting research. From this perspective, anger and hostility that emerge from interactions and relations between husband and wife come to contaminate the way parents relate to their children. From a more encouraging standpoint, feelings of satisfaction, pleasure, and love emanating from the partner relationship help fuel positive and growth-promoting parenting practices.

A great deal of marriage-parenting research can be interpreted in terms of affective spillover, such as Goldberg et al.'s (2002) recent finding of a positive and significant association between self-reported marital adjustment and the expression of affection by fathers when interacting with their 6-month-olds. But it is rare for the measures of marriage and parenting to be affect-specific, as many focus on general marital quality or satisfaction (Grych, 2002). Easterbrooks and Emde (1988) provide a fortunate exception. In their study of the transition to parenthood, marital harmony, measured via observational assessments of spousal interaction, proved related to the affect-sharing, physical affection, and expression of approval that parents evinced while interacting with their infants.

Negative affective spillover also characterizes the marriage-parenting relationship. But feelings of negativity in the marriage may not always take an identical form in the parent-child relationship. In fact, rather than anger experienced in the marriage manifesting itself directly in the parent-child relationship, it may foster withdrawal. Parents who are distressed and overwhelmed by difficulties in their marriage may simply lack the emotional energy to engage their children. Osborne and Fincham (1996) noted that when this happens, lax or permissive parents can be experienced by their children as rejecting. Evidence indicates, interestingly, that greater interparental hostility is related to withdrawal in the parent-child relationship (Lindahl, Clements, & Markman, 1997; Lindahl & Malik, 1999) and that spouse's withdrawal during marital conflict is related to greater hostility and intrusiveness with children (Katz & Gottman, 1996; Lindahl & Malik, 1999).

Stress and Coping

Although, in theory at least, a marriage in contemporary culture is supposed to nurture and support the self, the sad fact of the matter is that all too often it is a source of stress that overwhelms the coping capacities of the adults involved (Belsky, 1984). Thus, parents who are busy dealing with a troubled marriage lack the energy and attention required to deal with children in sensitive, supportive ways. Of course, stress that overwhelms or even challenges cop-

ing capacities can evoke negative emotion, and so spillover processes and stress-coping ones can be difficult to distinguish when it comes to accounting for the impact of the marital relationship on parenting. Grych and Clark (1999) documented the undermining effects of marital stress in showing that when infants were 1 year of age and costs emanating from the marriage were high (e.g., fighting, being criticized) and rewards low (e.g., good communication, effective conflict resolution), fathers found it more difficult to balance parenting with other roles and responsibilities, felt less competent as a parent, and found interacting with the infant less rewarding.

But in addition to marriage serving as a source of stress, well-functioning marriages can function as a source of support. In a good marriage, the partner not only provides love, attention, and consideration, but is instrumentally helpful, too. Such activities and experiences can foster the very energy, attention, and motivation that is essential for the continual provision of growth-supporting parenting. Consider, in this regard, Cox, Owen, Lewis, and Henderson's (1989) findings showing that when marital partners experienced greater emotional closeness, as reflected in shared ideas and activities, expressed affection and appreciation, and mutual confiding, mothers evinced greater warmth and sensitivity when interacting with their infant daughters (but not sons) and fathers manifested more positive attitudes toward the infant and the parenting role (though no effect on fathering behavior was detected).

A supportive marriage can also serve to protect or buffer the parent-child relationship from stresses emanating from other sources (Belsky, 1984), whether it be the parent's experience at work, relations with friends and relatives, or even dealings with other children. When considered from this perspective, a well-functioning marriage can enable a parent who might otherwise prove to be less attentive, caring, and affectionate with his or her child to sustain such qualities in the face of challenges emanating from outside of the marital relationship. Some of the most compelling evidence for such an effect comes from Crockenberg and McClusky's (1986) research showing that the otherwise detectable and negative effect of the infant's difficult temperament on the quality of mothering received was not evident when high levels of spouse support were in evidence.

Family Systems Theory

Family systems theory is actually less a theory, at least as drawn on by empirically minded family researchers, than a philosophical perspective derived from Von Bertalanffy's (1950) writings about general systems theory by family therapists struggling to understand linkages between dis-

tressed marriages and disordered children (S. Minuchin, 1974). Central to the theory/perspective is the notion that the family system comprises hierarchically ordered power relations among its members (i.e., parents, children) and "boundaries" that shape the ways interactions among members of varying status (should) take place. Also important is the notion of bidirectional and even circular causal processes, rather than simple linear ones, and the prospect that as open systems, families are subject to influence—both supportive and undermining—of forces emanating from outside of the family (e.g., the workplace, the school, the neighborhood; Cox & Paley, 1997; P. Minuchin, 1985).

Students of family systems theory highlight two processes to account for why troubled marriages may undermine growth-promoting parenting (and the converse). Adult partners whose emotional needs go unmet, or are insufficiently met, in the spousal relation are hypothesized to compensate by seeking a more intimate relationship with their child, risking the development of an enmeshed or excessively close relationship that fails to provide sufficient autonomy, especially psychological autonomy, to the child. The prospect also arises that as a result of a problematic relationship between the child and one parent, the other parent endeavors to make up for this liability through excessive involvement with the child.

There are certainly data that are consistent with such thinking. Consider, in this regard, Belsky, Youngblade, Rovine, and Volling's (1991) finding from a study of more than 100 families raising toddlers that when an intrusive father-child relationship coincided with a deteriorating marital relationship, the mother-child relationship often appeared very positive, characterized by high (and perhaps too high) levels of positive and facilitative behavior directed by the mother to the child. Of course, rather than reflecting an effort by the mother to compensate for the problematic father-child relationship, such results might be a function of mother's attempt to compensate for a dissatisfying marriage, which itself undermined the father's sensitivity to the needs of the child (Grych, 2002). Such an interpretation would be in line with Engfer's (1988) finding that mothers reporting high levels of marital conflict when infants were 4 months of age, also reported greater emotional involvement and proved to be more protective of their children 14 months later than other mothers.

Family therapists working from a family systems framework have also emphasized boundary-violation processes such as triangulation, detouring, and scapegoating in an attempt to explain marriage-parenting relations (Grych, 2002). Triangulation refers to a cross-boundary process whereby husband-wife conflict is avoided by involving the

child (S. Minuchin, 1974). When detouring or scapegoating characterizes this form of family dysfunction, the child becomes the focus of problems, particularly his or her supposedly troublesome behavior or illness, and difficulties in the marital/partner relationship itself are ignored. One anticipated consequence of such detouring is increased hostility toward and/or overinvolvement with the child. It may also be the case that a cross-generational coalition is established between one parent and the child that serves to position the other parent as an outsider. Such diverted emotional involvement with the child can be excessive, generating enmeshment, which can itself be an additional source of conflict between husband and wife, as one spouse finds the other spouse's level of involvement with the child beyond what might be regarded as normal or appropriate (see Margolin, Oliver, & Medina, 2001). Studying this process, Christensen and Margolin (1988) found that in troubled marriages, cross-generational coalitions were more evident and that conflict in the marriage was likely to contaminate the parent-child relationship. Kerig (1995) reported similar results in a study in which parents represented through hand-drawn and interlocking circles the nature of family relationships, finding that when cross-generational coalitions were pronounced, so was marital conflict. In a relevant longitudinal study, Lindahl et al. (1997) discovered that when fathers contributed more to the negative escalation of marital conflict, 5 years later they were more likely to involve (i.e., triangulate) their child in a family discussion task inappropriately.

Conclusion: Cause or Correlation?

Drawing formal lines between the models and mechanisms discussed linking marriage and parenting can be challenging, basically because there are not strict boundaries between the various perspectives considered. Parents who are stressed, for example, are likely to get angry, and such anger can contaminate the parent-child relationship. When this happens, is it a result of affective spillover, inability to cope in the face of stress, boundary violations, or some combination of the three? In point of fact, it may prove difficult to identify pure forms of these processes, as they are so often inextricably linked.

But a bigger cause for concern may be that even when (correlational) evidence emerges consistent with these models of marriage-to-parenting influence, such as that to be considered next, it may be inappropriate to draw strong causal inferences. This is because a "common factor" might be responsible for both the nature of the marital relationship and the parent-child one (Grych, 2002). As Belsky (1984) noted, the fact that the same psychological

agent—the spouse/parent—is involved in both the marriage and the parent-child relationship raises the prospect that a "third variable" reflecting enduring dispositional characteristics of the adult may account for the apparent effect of marriage on parenting. After all, it is not unlikely that an individual who had difficulty sustaining an emotionally supportive relationship with a partner may bring some of those same liabilities to his or her relationship with the child. It should not be forgotten that the husband and father are (often) one and the same person, as are the mother and wife.

Certainly consistent with this point of view is evidence from Engfer's (1988) aforementioned study showing that the personal psychological characteristics of neuroticism, depressiveness, and composure were associated with indices of both marriage and of parenting. Relatedly, Caspi and Elder's (1988) analysis of data from the Berkeley Growth Study indicated that adult personality drives both the marital and the parent-child relationship. The fact that most studies of marriage and parenting fail to appreciate, at least empirically, that the person filling the marital and parental roles are one and the same makes unclear the extent to which marriage is only correlated with parenting, as opposed to influencing it. Cox and associates (1989) have addressed this issue, finding evidence that even after taking into consideration parents' mental health, marital closeness predicted fathers' attitudes toward parenting and maternal sensitivity in interacting with daughters.

Empirical Findings Linking Marriage and Parenting

Although it was the case that the first work linking marriage and child development focused on children old enough to be diagnosed with behavior problems, most of the initial work examining marriage and parenting focused on the infant years. This is because it was developmental psychologists interested in the father-infant relationship who first recognized the failure of students of the family and of child development to simultaneously study marriage, parenting, and child development (Belsky, 1981). Thus, it remains the case that most of the relevant research, as even the earlier discussion suggests, has focused on infants. In recent years, however, this developmental base has broadened. In what follows, we review—illustratively rather than exhaustively—research documenting linkages between marriage and parenting as a function of the child's developmental status, considering first work on parent-infant relationships, then parent-child relationships, and finally parent-adolescent relationships. Thereafter, very recent work looking at

what happens to parenting when the marital relationship turns violent is considered.

The Infant/Toddler Years

Sensitive-responsive parenting has been identified as promoting a secure infant-parent attachment, and cognitively stimulating interchanges between parent and infant/toddler have been identified as promoting early cognitive and language development. Thus, it is not surprising that these are the targets of parenting and of the parent-child relationships that investigators focused on during the child's first 2 to 3 years of life. Perhaps the earliest study was that reported by Pedersen (1975, 1982; Pedersen, Anderson, & Cain, 1977), now almost 3 decades old, showing that tension and conflict between husband and wife—as reported by fathers—predicted less observed maternal sensitivity and responsiveness when feeding the infant, whereas husband's esteem for the wife as a mother, reflecting direct emotional support, predicted greater maternal feeding competence.

As already noted, work by Cox and associates (1989), who measured marital closeness and intimacy by means of observational and self-report measures, demonstrated that such linkages between marriage and observed parent-infant interaction could not be fully explained by parental mental health, thereby suggesting a truly causal role for the marriage in shaping parenting. In a somewhat later study, Heinicke (1984) found that marital adjustment measured before the infant was even born predicted greater parental responsiveness to the child's needs (but not parental cognitive stimulation), not only when the child was 1 month of age, but 4 years later. In another study of the transition to parenthood, Cowan and Cowan (1992) observed that the more marital quality declined through the first 18 months postpartum, the more cold, competitive, and angry were marital interactions when children were 3.5 years of age; such patterning of marital conflict was itself related to lower expressions of warmth toward the child by mother and father, especially toward daughters. Notable is that in research on mothers rearing chronically undernourished infants in urban poverty in Chile, Valenzuela (1997) also found that marital satisfaction predicted greater maternal sensitivity.

In contrast to being sensitively responsive, parenting of an infant can be ill timed and intrusive. When Belsky and associates (1991) observed the fathering of men whose marriage had been repeatedly measured from the last trimester of pregnancy through 3 years postpartum, they found that men whose marriage decreased in love and whose feelings about their marital relationship increased in ambivalence more so than other men interacted with their

36-month-old children in a more affectively negative and overcontrolling-intrusive style than did other men (see also Cowan & Cowan, 1992). The fact that no similar relations emerged in the case of mothers in the Belsky et al. investigation, a result consistent with those from an earlier cross-sectional study of marriage and parenting (Belsky, 1979), seemed consistent with Belsky's conclusion that fathering may be more susceptible to marital influence than mothering, perhaps because fathering, especially during the infant years, is less scripted by social convention. Such differential results for mothers and fathers also emerged in Goldberg and Easterbrooks's (1984) study of toddlers, as they observed that greater marital quality predicted greater paternal though not maternal sensitivity (see also Volling & Belsky, 1991).

Before embracing the notion that fathering is more susceptible to marital influence than mothering, it is necessary to call attention to Erel and Burman's (1995) meta-analysis of 68 studies addressing the relationship between marriage and parenting. Despite repeated indications that marriage-parenting relations were stronger in the case of fathers than mothers, they failed to detect evidence that parent gender moderated the sizable and significant marriage-parenting relationship they detected across studies of children of all ages. What they were not in a position to determine, however, even given the seemingly large sample size they had to work with, was whether differential marriage-parenting relationships might obtain for mothers and fathers at some developmental periods rather than at others. Also of note is that when Krishnakumar and Buehler (2000) carried out their own meta-analysis of 39 studies a few years later, focused exclusively on interparental conflict (i.e., not marital satisfaction, cohesion), they detected a stronger marriage-parenting relationship in the case of fathers.

Not all relevant studies of marriage and parenting during the infancy period focus on parenting per se, as some research examines the quality of the parent-child relationship, usually by measuring the security of the infant-parent attachment relationship. This work also highlights positive associations between well- (or poorly) functioning marriages and well- (or poorly) functioning parent-child relationships. Indeed, three separate studies indicate that secure infant-parent attachment is related to higher marital quality, either measured contemporaneously (Goldberg & Easterbrooks, 1984), earlier in time (Howes & Markman, 1989), or repeatedly over time (Belsky & Isabella, 1988). Thus, for example, Howe and Markman observed that higher levels of marital satisfaction and communication quality and lower levels of interparental conflict were associated with secure rather

than insecure attachments, and Isabella and Belsky (1985) found that deteriorating marital quality was related to insecure infant-mother (though not infant-father) attachment.

The Preschool and Childhood Years

Investigations linking marital relations and parenting during the preschool and middle childhood years are generally consistent with those just summarized that focus on parenting during the first 3 years of life. Two classic studies meriting attention are one by Bandura and Walters (1959) showing that mothers inclined to nag and scold their sons felt less warmth and affection toward their husband, and another by Sears, Maccoby, and Levin (1957) indicating that mothers' professed esteem for their husband is systematically related to the praise they direct at their preschool children. More recently, Katz and Gottman (1996) observed dyadic and triadic family interaction in households with 4- to 5-year-old children; they found that hostility in the marriage predicted father intrusiveness and reduced levels of father involvement. When fathers withdrew from marital conflict, mothers were found to be more intrusive and critical of their young children but less involved in interacting with them.

Lindahl and Malik (1999) also documented the relationship between troubled marriage and problematic fathering in their study of Latin American and European American families rearing 7- to 11-year-old boys. Fathers in couples showing destructive conflict styles during a marital interaction task (as opposed to harmonious or disengaged styles) evinced greater rejection and withdrawal when observed interacting with their sons, and this was especially so when marriages were otherwise characterized as highly distressed. In an earlier study, this one of parents of 4.5- to 6.5-year-olds, Stoneman, Brody, and Burke (1989) found that fathers who were in happier and less conflicted marriages proved more consistent in enforcing limits placed on child behavior, a pattern of parenting known to increase the likelihood of children's complying with parental directives. More recently, Harrist and Ainslie (1998) reported that marital conflict predicted lower-quality interactions between parents and their children. In the course of studying the determinants of sibling relations, two separate teams of investigators detected linkages between marriage and parenting. Erel, Margolin, and John (1998) found that, in families with 3- to 8-year-olds, negative marital relations forecast elevated levels of maternal power assertion; Stocker and Youngblade (1999) reported that marital conflict predicted maternal and paternal hostility toward 7- and 10-year-olds. When Katz and Woodin (2002) drew distinctions between couples rearing 4- to 5-year-olds on

the basis of communication during a high-conflict marital discussion task, they found that spouses who emphasized the negative when speaking to their partner and who were poor listeners were most likely to issue commands to their offspring during a family interaction assessment.

Although the general trend is for marital quality and parenting to be positively related, such that poorer-functioning marriages and parent-child relations go together, this is not always the case. In the research by Stoneman et al. (1989), for example, parents of boys in happier marriages were more likely than those in less happy marriages to rely on authoritarian discipline, and fathers who reported more conflict in their marriage were less likely to report relying on authoritarian disciplinary strategies than other fathers. Moreover, and consistent with family systems conceptions of boundary violations, Brody, Pillegrini, and Sigel (1986) reported in a study of parent-child interaction during book reading and teaching tasks that the more conflict mothers reported in their marriage, the more engaged they were while teaching their 5.5- to 7.5-year-old children, asking more questions, offering more information, and providing more positive feedback. Belsky et al. (1991) drew attention to this work on finding, in their own study of parenting 3-year-olds during a teaching task, that declines in marital satisfaction across the transition to parenthood were associated with positive and facilitative parenting.

Clearly, it would be a mistake to conclude that parenting is invariably more supportive, warmer, and less rejecting in the preschool and middle childhood years when parents are happier or more satisfied in their marriage. Nevertheless, this does appear to be the main trend in the evidence. The exceptions to the rule raise interesting questions about the conditions under which, to say nothing of the mechanisms by which, anticipated relationships between marriage and parenting are just the opposite of what was expected (at least by spillover and stress and coping perspectives).

The Adolescent Years

It is only relatively recently that the interrelationship of marriage and parenting during the adolescent years has attracted empirical attention. Major parenting issues during this developmental period follow on from those of the middle childhood years, having to do with the management of discipline and, especially, the child's emerging autonomy (in the face of dramatic biological and social changes). Thus, concern is not only for whether parents enact authoritative parenting practices characterized by high levels of warmth and control or authoritarian ones (low warmth, high control), but also whether they monitor their child's whereabouts. Parents who score low on control but high on

warmth are often regarded as permissive, and those low in both warmth and control as neglectful.

Harold and Conger (1997; Harold, Fincham, Osborne, & Conger, 1997) examined the relationship between marital quality and parental rejection in a short-term longitudinal study of more than 400 seventh-grade children living in rural Iowa. Couples that evinced more hostility during the course of a husband-wife interaction episode (i.e., being critical, shouting, yelling, expressing anger) were, according to adolescent reports, more rejecting as parents 1 year later. These results were consistent with those obtained by Fauber, Forehand, Thomas, and Wiersen (1990), who observed that higher levels of interparental conflict predicted greater maternal rejection and psychological control (but not lax control), as measured via videotaped interactions of mother and teen and teen reports of parenting, in their analysis of 46 maritally intact families rearing 11- to 15-year-olds. A much larger study based on a nationally representative survey of almost 1,000 families rearing 12- to 18-year-olds also reported marital conflict to predict greater use of harsh discipline by parents and, relatedly, more parent-adolescent conflict, findings generally consistent with, though somewhat stronger than, those emanating from similar analyses carried out on subsamples of families rearing 2- to 4-year-olds ($n = 623$) and 5- to 11-year-olds ($n = 974$; Buehler & Gerard, 2002). Of note, too, is that these relationships between marital conflict and ineffective parenting characterize both poor families and those who were not economically distressed.

Domestic Violence and Parenting

Although, as the preceding summary of research on marriage and parenting reveals, a good deal of attention has been devoted to investigating linkages between marital conflict and parenting, only recently have family researchers come to study parenting in the context of domestic violence. It can be argued that domestic violence should be distinguished from marital conflict rather than be judged as simply an extreme form of spousal discord (Jouriles, Norwood, McDonald, & Peters, 2001; Levendosky et al., 2003; Rossman, 1998). This is because of the traumatic impact of witnessing violence (e.g., Levendosky, Huth-Bocks, Semel, & Shapiro, 2002; Rossman, 1998), as well as the fact that whereas conflict is universal in marriage, at least to some degree, violence is not.

Violence between intimate partners, it turns out, is far more frequent than many would like to believe. Incident rates for violence from a romantic partner are approximately 16%, depending on whether only married or both married

and dating couples are the focus of consideration (Morse, 1995; Straus & Gelles, 1986). Prevalence rates range from 9% to 66%, depending again on the definition of the partner (Brown et al., 1998). In their work relying on a National Institute of Justice database covering five major U.S. cities, Fantuzzo and associates (1991) found that children are disproportionately represented in households in which women are abused.

A multiplicity of studies now show that such exposure is detrimental to children's well-being. Young children (i.e., 3 to 5 years) have increased trauma and dissociative symptoms relative to children in nonviolent homes (Rossman, 1998), as well as lower self-esteem, lower levels of social functioning, and higher levels of depression and anxiety relative to children in nonviolent families (Fantuzzo et al., 1991; Hughes, 1988; Staggs, Wills, & Howell, 1989). The possibility that at least some of these correlates of exposure to domestic violence are mediated by parenting comes from two sets of work. The first, indirect evidence derives from studies linking domestic violence with parenting, showing that mothers who are victims of partner abuse provide less emotional support to their school-age children than counterparts who do not experience domestic violence, and this is so irrespective of whether mothering is measured via parent and child report (McCloskey, Figueredo, & Koss, 1995) or via observation of mother-child interaction (Levendosky & Graham-Berman, 2000). In this latter work, the investigators directly examined the role of parenting in mediating the effect of domestic violence on child functioning, showing, via (cross-sectional) path analysis, that domestic violence predicted less effective parenting and, thereby, elevated levels of problem behavior. Additionally, and also consistent with Belsky's (1984) model of the determinants of parenting, domestic violence affected parenting and thereby child aggression and disobedience by undermining maternal psychological well-being (i.e., depression, posttraumatic stress).

Conclusion

Whether one considers marital conflict, domestic violence, or other aspects of the marital relationship, including satisfaction, communication, or overall quality, or whether one considers parental sensitive responsiveness, warmth, control, harsh discipline, or a host of other features of parenting, linkages emerge between marriage and parenting. And as we have seen, this is so across the infant/toddler, preschool/middle childhood, and adolescent years. For the most part, though not exclusively, the evidence points to problematic marriages and problematic

parenting co-occurring; the evidence for compensation in which parenting looks positive in response to troublesome marital processes is far more limited. Notable from the perspective of the child is that parental emotional unavailability (e.g., rejection, hostility, unresponsiveness), poor behavioral control (e.g., lax monitoring, inconsistent or harsh discipline), and psychological control (e.g., guilt induction, love withdrawal, dominating conversations) have been found to mediate, at least partially, the relationship between interparental conflict and other aspects of the marriage and child adjustment (e.g., Buehler & Gerard, 2002; Fauber et al., 1990; Harold et al., 1997), consistent with Belsky's (1981, 1984) formulations of the interrelationships of marriage, parenting, and child development (but see Frosch & Mangelsdorf, 2001, for an exception).

THE NEIGHBORHOOD

Research on neighborhood conditions and family functioning has been heavily influenced by urban sociological models of how neighborhoods and communities affect individual behavior (Coleman, 1988; Jencks & Mayer, 1990; Sampson, 1992; C. R. Shaw & McKay, 1942; W. J. Wilson, 1987, 1991) and by ecological models of human development in context (Belsky, 1984; Bronfenbrenner, 1979). Integrating these theoretical strands, developmentalists have explored how children's outcomes, including infant mortality, academic achievement, social competence, school dropout, teen childbearing, and delinquency, are influenced not only by the family context, but also by neighborhood structural characteristics (see Leventhal & Brooks-Gunn, 2000, 2003, for a review). Implicit in this research is the hypothesis that positive child outcomes depend on the skill with which parents buffer their children from the daily stresses of living in poor and dangerous neighborhoods (Furstenberg et al., 1993; Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999; Garbarino & Kostelny, 1993). Yet, relatively few studies have explicitly modeled the degree to which parenting practices mediate or moderate the effects of neighborhood conditions on children's outcomes (Burton & Jarrett, 2000). In part, this reflects the focus of research on adolescents' as opposed to younger children's outcomes. Whereas most adolescents are regularly exposed to nonparental influences in school and the community, younger children are less likely to be exposed to neighborhood influences without their parents' knowledge (Klebanov, Brooks-Gunn, Chase-Lansdale, & Gordon, 1997). Thus, parents are likely to play a stronger

role in mediating the effects of neighborhood conditions on young children's development than they do for older children. In this section, we review the literature on how neighborhood conditions affect parenting behavior. That a disproportionate number of the studies reviewed in this section focus on how parenting is affected by living in poor and dangerous neighborhoods (as opposed to affluent neighborhoods) reflects the focus in this literature. A future direction for research may be to understand the ways affluent neighborhoods affect parenting. Conceptual and methodological limitations of this research are discussed at the end of the section.

Conceptions of How Neighborhoods Affect Parenting

W. J. Wilson (1987, 1991) has argued that living in neighborhoods characterized by high rates of unemployment, poverty, and single motherhood results in what he has termed "social isolation" from mainstream jobs and lifestyles. Social isolation can lead to family practices that do not foster the skills children need for success in school and work. Whereas parents in affluent neighborhoods emphasize the importance of daily routines, future goals, school and work skills, and parental self-efficacy, the efforts of poor families to foster these same skills are hindered by structural features of their communities that result in their isolation from formal and informal networks of support.

Consistent with Wilson's conceptualization of social isolation, Sampson and colleagues (Sampson, 1992; Sampson & Groves, 1989) contend that neighborhoods characterized by poverty, high residential turnover, and ethnic heterogeneity are vulnerable to social disorganization, meaning that these communities often fail to realize the common values of their residents or to maintain effective social controls over individual members. Families in socially disorganized communities lack social capital, a concept introduced by Coleman (1988) to refer to the network of relationships that allow individuals to achieve particular goals. Communities rich in social capital are characterized by an extensive set of obligations, expectations, and social networks that connect adults within the community and foster their ability to supervise and monitor children. Sampson and colleagues argue that socially disorganized neighborhoods promote an individualistic style of parenting in which families tend to isolate themselves and their children from the surrounding community and distrust local schools and services. In sum, families in poor communities often lack the formal and informal networks that provide them with material and social resources and that

enable them to foster the skills their children need for educational and labor market success.

Neighborhoods and Parenting

Sampson's (1992; Sampson & Groves, 1989) theory of social disorganization is supported by ethnographic work conducted among Philadelphia neighborhoods. Furstenberg and associates (1993, 1999) found that poor, socially disorganized neighborhoods fostered a highly individualistic parenting style in which parents isolated themselves from neighbors, did not rely on neighborhood formal or informal institutions for help in raising their children, and spent enormous amounts of time personally monitoring, supervising, and controlling their children's behavior. In more cohesive neighborhoods, where parents and their friends and relatives had lived for several generations, parents perceived a neighborhood consensus about child-rearing values that made them more willing to entrust their children's care to formal and informal neighborhood networks. In these more cohesive neighborhoods, parents often took responsibility for supervising and monitoring children who were not their own. In contrast, what Furstenberg termed "super-motivated parenting" was required of parents in socially disorganized neighborhoods to protect their children from neighborhood dangers and to provide adequate opportunities (often located outside of their own neighborhoods) for their children (Furstenberg et al., 1993; Garbarino & Kostelny, 1993). Furstenberg noted that parents with ordinary levels of parental motivation would probably be able to create better opportunities for their children were they to live in neighborhoods that provided better resources and more support, a proposition to which we return in the section on experimental evaluations of neighborhood effects.

Qualitative studies of families in poor neighborhoods (Furstenberg et al., 1993, 1999; Jarrett, 1997) are consistent in showing that residence in poor, socially disorganized neighborhoods is associated with parenting practices that can be effective in the short term in promoting children's competencies and protecting children from undesirable influences. However, these family practices place an enormous burden on parents, whose often rational distrust of neighbors and community services leads them to isolate themselves and their families from potential sources of support. Moreover, by keeping children close to home, parents may unintentionally deprive them of opportunities for social interaction and physical exercise that may, ultimately, promote children's social mobility (Furstenberg et al., 1993; Garbarino & Kostelny, 1993).

Quantitative studies of how neighborhood conditions affect normative parenting behavior are scarce. However, the available data converge in showing that neighborhood characteristics such as poverty, joblessness, ethnic diversity, dissatisfaction with neighborhood conditions, and low affluence are associated with lower levels of parental warmth (Ceballo & McLoyd, 2002; Klebanov et al., 1997; Klebanov, Brooks-Gunn, & Duncan, 1994; Pinderhughes, Nix, Foster, Jones, & The Conduct Problems Prevention Group, 2001; Simons, Johnson, Conger, & Lorenz, 1997), more harsh and inconsistent discipline (Hill & Herman-Stahl, 2002; Pinderhughes et al., 2001; Simons et al., 1997), poorer physical home environments (Klebanov et al., 1994, 1997), and lower levels of cognitive stimulation (Klebanov et al., 1997), even controlling for family and individual characteristics that could have more proximal influences on parenting. It bears noting, however, that across these studies the same neighborhood characteristics are rarely associated with the same parenting outcomes. Moreover, the degree to which neighborhood conditions affect parenting behavior may depend on individual, family, or other contextual characteristics. For example, Klebanov and colleagues (1997) reported that neighborhood economic disadvantage had a stronger negative effect on parenting quality for low-income compared to high-income families. Relatedly, Ceballo and McLoyd found that the receipt of social support was more weakly associated with maternal nurturance and a lower reliance on punitiveness in neighborhoods characterized by violent crime and poverty than in lower-risk neighborhoods.

In contrast to the literature on normative parenting behaviors, the child maltreatment literature, influenced by Bronfenbrenner's (1979) work on the ecology of human development, has long recognized that neighborhood socioeconomic and demographic factors are strongly associated with rates of child maltreatment (Belsky, 1980, 1993; Garbarino, 1977b). Children who live in neighborhoods characterized by poverty, violence, unemployment, excessive numbers of children per adult resident, population turnover, and a concentration of female-headed households are at the greatest risk of maltreatment (Coulton, Korbin, Su, & Chow, 1995; Deccio, Horner, & Wilson, 1994; Drake & Pandey, 1996; Garbarino & Sherman, 1980; Korbin, Coulton, Chard, Platt-Houston, & Su, 1998; Lynch & Cicchetti, 1998; Steinberg, Catalano, & Dooley, 1981; Zuravin, 1989).

Garbarino and colleagues (Garbarino, 1977a; Garbarino & Crouter, 1978; Garbarino & Kostelny, 1992; Garbarino & Sherman, 1980) have argued that sociodemographically high-risk neighborhoods vary in the extent to which they

are characterized by high rates of child maltreatment and neglect. Qualitative studies have shown that in poor neighborhoods where community leaders felt hopeful about their neighborhood's prospects, rates of maltreatment were lower than would be expected on the basis of the socioeconomic data alone (Garbarino & Kostelny, 1992). Apparently, social organization, especially the presence of supportive formal and informal networks, protected families from succumbing to neighborhood risk. However, other researchers have failed to replicate these findings. For example, Deccio and colleagues (1994) found no differences in perceived personal and parenting support among parents in neighborhoods that were demographically similar but differed in rates of child maltreatment. Still other researchers have questioned the direction of effects, noting that it is unclear whether abusive families lack social supports or simply fail to use them appropriately (Vondra, 1990). A number of researchers have shown that although abusive parents have extensive social networks, they are a drain on these networks and they discourage long-term relationships from forming (Crittenden, 1985; Vinson, Baldry, & Hargreaves, 1996; Vondra, 1990).

These failures to replicate and concerns about potential selection effects raise questions about the strength of the relationship between social support and child maltreatment (Seagull, 1987; Zuravin, 1989). Moreover, the child maltreatment literature has failed to show definitively that low social support and social disorganization are the mediating mechanisms by which neighborhood disadvantage results in child maltreatment. For example, using multilevel models, Coulton, Korbin, and Su (1999) found that structural characteristics of neighborhoods (e.g., impoverishment, child care burden) accounted for variation in child abuse potential beyond the effects of individual characteristics, but neighborhood *processes* (e.g., quality, facilities, disorder, lack of control of children) did not. In sum, research on neighborhood characteristics and child maltreatment has not advanced far beyond the state reported by Zuravin nearly 15 years ago in her review of the ecology of child maltreatment. That is, although researchers have demonstrated convincingly that rates of child maltreatment vary systematically with neighborhood conditions, more work is needed to specify potential confounding factors (e.g., selection and aggregation) and to identify the processes by which variations in neighborhood context are associated with variations in rates of maltreatment.

Some of the strongest evidence for the causal effects of neighborhoods on family functioning comes from experimental interventions in which families are offered the opportunity to relocate from low-income to higher-income

neighborhoods. These programs are based on the premise that improving a person's residential location will increase his or her access to resources and opportunities (Del Conte & Kling, 2001). The Moving to Opportunities (MTO) program, sponsored by the U.S. Department of Housing and Urban Development, offered families living in federally subsidized housing in five cities the opportunity to move to better neighborhoods. A unique feature of MTO was that those who volunteered for the program were randomly assigned to treatment and control groups with different subsidies and services. Data from a follow-up survey at the New York City site (Leventhal & Brooks-Gunn, 2001), conducted 3 years after the program began, showed that mothers who had moved out of public housing had increased employment, were less reliant on welfare compared to control mothers, and were less likely to report symptoms of depression and anxiety. Most important for this chapter, these mothers were less harsh in their parenting, and their children's lives had become more structured.

Poor Mental Health as a Mediator of Neighborhood Effects on Parenting

The stress of living in poor and dangerous neighborhoods where parents are exposed to many uncontrollable life events may affect parenting by contributing to symptoms of depression and anxiety (Cutrona, Russell, Murry, Hessling, & Brown, 2000) which was shown to undermine growth-promoting parenting in preceding sections of this chapter. Several researchers have reported that individuals who live in more disadvantaged neighborhoods report more symptoms of depression or psychological distress (Cutrona et al., 2000; Hill et al., 2002; O'Brien, Hassinger, & Dershem, 1994; Ross, 2000), and the association with mental health problems appears to be stronger for neighborhood social disorder (i.e., chaotic, crime-ridden neighborhoods) than for neighborhood cohesion (i.e., the sense that community members have a common stake in the neighborhood). Moreover, high-quality neighborhoods have been shown to amplify the effects of individuals' positive characteristics, and poor-quality neighborhoods have been shown to amplify the effects of individuals' negative characteristics on their psychological functioning (Cutrona et al., 2000).

Several studies, controlling for a range of family and individual characteristics, have shown that parents who live in disadvantaged, chaotic, and unsafe neighborhoods use less effective parenting strategies (e.g., harsh, inconsistent discipline, low monitoring, low warmth) because they are more depressed (Hill et al., 2002; Simons et al., 1997). However, other work suggests that neighborhood effects on

mental health and parenting may be principally a function of family income (Jones, Forehand, Brody, & Armistead, 2002). These findings are consistent with a large body of literature showing that mental health problems mediate the association between family-level disadvantage and parenting practices (see McLoyd, 1998, for a review).

Conceptual and Methodological Challenges to Neighborhood Research

A growing number of quantitative and qualitative studies, driven by a well-developed theoretical framework, have linked neighborhood characteristics with parenting practices, even controlling for individual and family conditions. Nevertheless, interpretation of neighborhood effects on parenting practices and children's outcomes is challenged by a host of conceptual and methodological problems (Duncan, Connell, & Klebanov, 1997; Duncan & Raudenbush, 2001; Ginther, Haveman, & Wolfe, 2000; Manski, 1993; Tienda, 1991). The *simultaneity problem* refers to the phenomenon whereby neighborhood conditions are not only causes of, but are simultaneously caused by, individual characteristics. For example, as described by Duncan and Raudenbush, Sampson, Raudenbush, and Earls (1997) have shown that a sense of collective efficacy among adults in a neighborhood deters youth problem behaviors. It is possible, however, that the sense of collective efficacy is derived, in part, by the low level of youth behavior problems in the community and that an increase in delinquency might undermine this sense of control. The *omitted-context-variables problem* refers to the possibility that models of neighborhood effects fail to estimate other important sources of contextual variation that are associated with the outcome in question. A related problem is the *endogenous membership problem*, which refers to the possibility that neighborhood conditions may simply reflect characteristics of the individuals who select themselves into those neighborhoods. For example, neighborhood poverty may be associated with suboptimal parenting practices because the parents who lack the wherewithal to escape poor and dangerous neighborhoods also lack the skills to provide competent parenting. The problem of modeling *the role of family demographic characteristics and processes* in neighborhood research refers to the need to move beyond tests of neighborhood conditions as direct effects on individual outcomes and to test whether neighborhood effects are mediated by or moderate other, more proximal processes. Finally, the problem of *obtaining sufficient variability in neighborhood contexts* refers to the need to measure a wide range of neighborhood contexts to move beyond simple assessments of a single "good" versus "bad" neighborhood dimension.

Essentially, these problems confound the estimation of neighborhood effects on parenting by potentially biasing the estimates, by creating problems of identification (e.g., when parenting outcomes are simultaneously caused by and causes of neighborhood conditions), and by producing statistically inefficient dependence across observations. As reviewed by Duncan and Raudenbush, these problems are not always intractable and can sometimes be adequately addressed in nonexperimental designs. They conclude, nevertheless, that experimental research on neighborhoods holds the most promise for accurately estimating neighborhood effects on parenting and children's outcomes.

Conclusion

There is ample theoretical reason to expect that neighborhood conditions should affect parenting, and the small empirical literature is generally consistent in demonstrating hypothesized effects. Nevertheless, the literature would benefit greatly from work that addresses the many conceptual and methodological problems that challenge this research. Better evidence for neighborhood effects on parenting and children's outcomes should come from experimental research on residential mobility, studies that use more sophisticated methods of analysis to deal with the methodological problems outlined here, and studies in which process variables are better measured and better conform to theory about how neighborhood conditions affect individual outcomes.

GENERAL CONCLUSION

As we have noted repeatedly throughout this chapter, it is difficult to conclude with any certainty that the factors considered in this review of research on the determinants of parenting truly operate in a classically causal fashion. With few exceptions, the research is based on correlational rather than experimental designs, so third-variable explanations often plague interpretation of results. Is it the case, for example, that personality causally contributes to parenting, or is any such association merely a function of common genes shaping personality and parenting? Relatedly, and illustratively, does marital quality or even neighborhood characteristics actually enhance or undermine parenting, or is it simply the case that certain kinds of people have certain kinds of marriages and/or select to live in particular kinds of neighborhoods, and that it is these selection processes that account for the associations detected in numerous studies between parenting and features of the marriage and the neighborhood? Such questions cannot be

answered in the case of most research conducted or reported in this review, yet there is sufficiently tantalizing experimental evidence and work that endeavored to control for alternative explanations that we think it remains as a good working hypothesis that the factors considered in this analysis do actually contribute to parenting that either fosters or undermines the psychological and behavioral development of children. Nevertheless, the fact that the data are not more conclusive highlights one of major needs of future research.

As we enter the twenty-first century, some might thus conclude that it is a sorry state of affairs indeed that characterizes what we know—and do not know—about the determinants of parenting, given the major limitation just cited of much of the work that has been discussed in this chapter. But before we conclude that the determinants-of-parenting glass is half empty, it seems worth taking stock of how this arena of inquiry has advanced, perhaps supporting a claim that half full might be a better characterization. Consider in this regard that relative to when Belsky (1984) first proposed his model of the determinants of parenting and reviewed evidence on which it was based, great progress has been made in (1) including fathers in studies of parenting; (2) researching the parenting of children of school age and adolescents, not just infants and preschoolers; (3) considering the interactive role played by a variety of factors, so as to illuminate processes of amplification and buffering; (4) testing mediational processes linking determinants of parenting with child development outcomes or those linking one source of influence (e.g., marital quality) to another (e.g., psychological well-being) before being connected with parenting; and (5) conducting in some cases experimental research to illuminate causal processes and making efforts to discount alternative explanations by means of statistical control.

In light of all this progress that has been made, it remains as true today as it was 2 decades ago that parenting is multiply determined by forces that emanate from the child, the parent, and the social context; that these forces not only additively contribute to parenting, but interact to amplify and buffer the effects of one another; and that the factors often mediate one another so that parenting is likely to be influenced directly and/or indirectly by attributes of the child, the parent, and the social context (Belsky, 1984). It remains the case, as well, that these lessons, which originated in the study of the etiology of child maltreatment (Belsky & Vondra, 1988), clearly extend to parenting that is not disturbed (i.e., in the normal range of variation). As such, this entire body of work reminds us that if the goal is to enhance child development by enhancing parenting,

there are many handles for interventionists to grab on to and manipulate. Indeed, a fundamental take-home message for the applied developmentalist or clinician must be that efforts to enhance parenting and child development should be targeted to more than a single source of influence, as it is invariably the cumulative impact of the multiple sources of influence considered herein (and others: social support, occupational experiences) that determine the course of parenting, parent-child relations, and child development to a substantial degree.

The effects of interparental discord on children's psychological adjustment has been a long-standing concern for scientists and practitioners across multiple disciplines in psychology, sociology, psychiatry, and epidemiology. The first generation of research on the interplay between interparental and child functioning was largely guided by two interlocking questions: Is the quality of the marital or interparental relationship associated with child psychological adjustment? And, if so, what is the nature of the risk in terms of its magnitude (i.e., effect size) and scope (i.e., applicability across domains of functioning) of effect? In addressing these questions, seminal studies in the 1930s and 1940s repeatedly documented links between marital dis-

cord and child psychological problems (e.g., Baruch & Wilcox, 1944; Towle, 1931).

Following a notable hiatus in research conducted on interparental and child functioning, researchers revisited and expanded on these research questions during the 1960s and 1970s. With marked rises in U.S. divorce rates during this period, a central objective was to unpack the multidimensional nature of marital dissolution by determining the relative risk posed by parent-child separation and interparental conflict to children's adjustment (Gregory, 1965; Hetherington, Cox, & Cox, 1976; Jacobson, 1978). By consistently supporting the hypothesis that interparental conflict was a stronger predictor of child psychological problems than parent-child separation per se, this body of work prompted a new sense of interest and urgency in studying the impact of interparental conflict

Preparation of this chapter was supported by the National Institute of Mental Health grants MH 57318 and MH 71256.

on children (Amato & Keith, 1991; Emery, 1982; Rutter, 1971). As Jaffe, Wolfe, and Wilson (1990, p. 33) aptly noted of the 1980s, "It was not until the past decade that family discord and spousal violence reached center stage as possible predeterminants of developmental psychopathology." During the 1980s, researchers specifically expanded research directions by systematically examining the generalizability or specificity of associations between different characteristics of interparental functioning and various dimensions of child functioning. These studies showed that interparental discord was associated with increased psychological difficulties across a wide developmental period encompassing infancy through young adulthood. Moreover, the vulnerability of children from high-conflict homes was demonstrated to be prevalent across a wide spectrum of functioning, as evidenced by elevated rates of social difficulties, behavioral problems, emotional symptoms, academic impairments, and psychophysiological reactivity.

Quantitative and qualitative reviews of this cumulative body of research have indicated that associations between interparental conflict and child maladjustment were generally small to medium in magnitude across a broad array of domains of psychological adjustment (Buehler, Anthony, Krishnakumar, & Stone, 1997; Grych & Fincham, 1990). In their qualitative review of the literature, Grych and Fincham reported that interparental conflict predicted between 4% and 20% of individual differences in children's functioning. In expanding on these conclusions, a meta-analysis evaluating the findings from a broader sampling of studies indicated that the effect size of the relationship between interparental conflict and child functioning was modest to moderate in magnitude (Buehler et al., 1997).

Guided by the consistency of the risk posed by marital conflict, many researchers have redirected their attention toward conducting a second generation of research. Rather than continuing to address the question of whether interparental difficulties are a risk factor for children, researchers over the past 2 decades have increasingly focused efforts on understanding how and why interparental discord is associated with child adjustment problems. Thus, a key component of this process-oriented research agenda is to identify the mechanisms and processes that explain or account for the vulnerability of children exposed to high levels of interparental discord. By the same token, the relatively modest magnitude of the developmental risk accompanying exposure to interparental discord also reflects that children exposed to similar levels of interparental stress evidence considerable variability in

their functioning. Consequently, another central component of the second generation of research is to identify the sources of heterogeneity in the outcomes of children. To address these process-oriented issues, scholarship in this second generation of research has evolved toward developing and testing more complex and sophisticated models of the interplay between interparental and child functioning (E. M. Cummings & Cummings, 1988; Fincham, 1994).

The overarching objective of this chapter is to illustrate how the principles, assumptions, and aims of developmental psychopathology can inform and advance current and future research directions in the interparental discord literature. To achieve this objective, the first part of the chapter provides a brief overview of a conceptual framework inspired by a developmental psychopathology perspective on interparental discord. In the second part, we review the large corpus of literature on the relationship between interparental and child functioning through the lens of our developmental psychopathology framework. Guided by the aims, principles, and concepts of developmental psychopathology, we specifically examine the developmental implications of interparental conflict in a larger biopsychosocial constellation of risk and protection. In the final part of the chapter, we address how the developmental psychopathology perspective may also serve as a heuristic for generating new conceptual and methodological directions in interparental discord research.

A DEVELOPMENTAL PSYCHOPATHOLOGY APPROACH TO UNDERSTANDING INTERPARENTAL DISCORD

The principles and aims of developmental psychopathology can provide valuable directions for developing, refining, and testing the interplay between interparental and child functioning. Transactional approaches to developmental psychopathology share the trademark assumption that child adaptation to adversity is an evolving product of a dynamic child in an ever-changing, multilayered ecological context. Understanding the nature of developmental trajectories of child adaptation requires an appreciation of the ongoing bidirectional exchanges of biopsychosocial resources and liabilities between the child and the multi-level, multivariate network of family and ecological factors. There is no simple one-to-one correspondence between a given risk factor such as interparental discord and a specific child outcome. Rather, consistent with the

concept of developmental pluralism, individual differences in the interplay between the child and contextual characteristics conspire to engender multiple pathways toward normal and abnormal functioning. The mutually informative value of studying both normal and abnormal development necessitates a complementary focus on positive (e.g., protective) factors and outcomes (e.g., competence in the face of risk) and negative (e.g., risk and potentiating) factors and outcomes (e.g., psychopathology).

Two concepts have been enlisted from developmental systems theories to characterize the multiplicity of paths between risk factors and outcomes in developmental psychopathology (Cicchetti & Rogosch, 1996). First, the concept of *equifinality* specifically refers to the notion that a single outcome can be the result of multiple factors and processes. For example, children's success in sustaining competence in the face of interparental adversity may result from any number of child processes (e.g., ability to regulate emotion) or interpersonal conditions (e.g., supportive parent-child relationship). Second, *multifinality* reflects the notion that a diverse set of outcomes may result from a common factor or pathway. Thus, even children exposed to highly similar patterns of interparental discord are expected to evidence substantial variability in their outcomes by virtue of their different intrapersonal attributes, psychosocial resources, and multivariate constellations of risk. Consequently, there is a multitude of ways of developing along adaptive and maladaptive trajectories, as development may involve different starts and stops, directions toward competence and disorder as children get older. The developmental course of each child is to some degree unique due to the specific transactions between his or her prior and current experiences in family and ecological contexts and his or her own attributes, resources, and histories of adaptation. It follows that change in functioning can be lawfully predicted and explained at least in part by elucidating the nature of the interplay between the child and the environment. Although change is always to some extent possible, the concept of canalization specifies that the magnitude and quality of change is constrained by organizational adaptations resulting from past transactions between the child and contexts of development (Waddington, 1957). Thus, under the broad boundaries of developmental psychopathology, the rule of thumb is that "the longer an individual continues along a maladaptive ontogenetic pathway, the more difficult it is to reclaim a normal developmental trajectory" (Cicchetti & Cohen, 1995, p. 7). Likewise, individuals experiencing longer histories of adaptive pathways can withstand greater challenges to their psychological adjustment.

In applying this concept of development to the study of children exposed to interparental discord, Figure 3.1 is designed to provide a parsimonious illustration of the dynamic interplay between interparental relations and children's developmental outcomes in the broader organizational context of child attributes, family processes, and ecological characteristics. The model specifically proposes that interparental conflict increases child vulnerability to maladaptive trajectories through multiple mechanisms and pathways. Two specific classes of process models are especially useful tools for explicating the effects of these mechanisms. Mediational models, which constitute the first class of process models, are designed to determine *how* or *why* a particular factor, such as interparental conflict, poses a risk for child adjustment. Mediators are the *generative mechanisms* through which independent variables affect outcomes (Baron & Kenny, 1986; Holmbeck, 1997, 2002). Thus, in the parental conflict literature, a new generation of research has involved identifying the mechanisms and processes that explain how and why interparental conflict is associated with forms of child maladjustment. Analytically, identifying a mediator requires demonstrating that the focal process variable explains substantial amounts of variance in the link between interparental difficulties and child maladjustment.

Moderator models are the second class of process models that assist in the identification of diverse pathways and trajectories in associations between interparental relations and child adjustment. Moderator models specifically address the question of when a specific risk factor is most or least likely to be associated with a particular outcome. Thus, identifying whether the strength or direction of relations between an independent variable (e.g., interparental conflict) and a dependent variable (e.g., child functioning) varies at different levels of another variable is the principal aim of moderator models (Baron & Kenny, 1986; Holmbeck, 1997, 2002). Risk and protective frameworks of developmental psychopathology have distinguished between two specific types of moderators: protective factors and potentiating factors. Protective factors or buffers reflect factors that reduce or offset the risk associated with exposure to interparental discord. Conversely, potentiating factors are moderators that amplify the association between interparental conflict and child maladjustment.

Consistent with the mediator models, Path 1 in Figure 3.1 illustrates the assumption that the stressfulness of exposure to interparental difficulties directly sets in motion processes within children that ultimately increase their

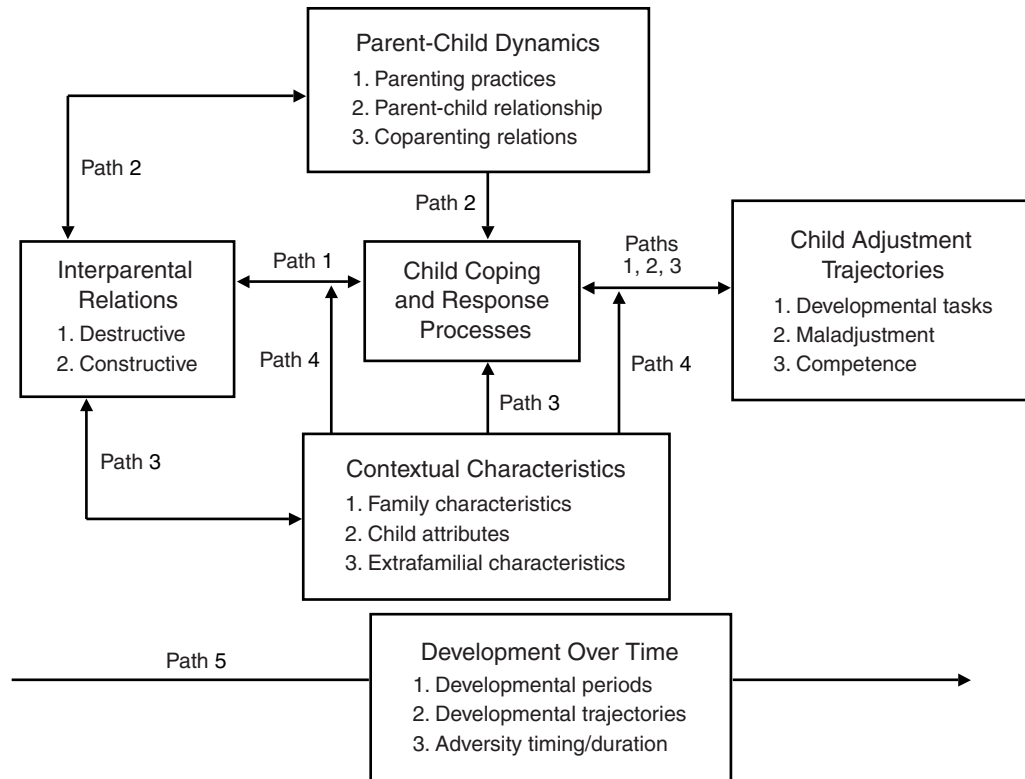

Figure 3.1 A model of the dynamic interplay between interparental relations and children's developmental outcomes in the broader organizational context of child attributes, family processes, and ecological characteristics.

risk for psychological problems. In the direct path component of our model, exposure to interparental discord is thought to undermine child mental health and welfare by engendering more maladaptive response patterns to interparental and family stress. Changes in children's response patterns to interparental and family stress are theorized to vary as a function of their exposure to specific dimensions of interparental conflict. Our model is therefore designed to highlight the utility of distinguishing between constructive and destructive characteristics of the conflict from the child's perspective. Specific experiential histories with these conflict characteristics are proposed to change children's reactivity to subsequent bouts of family and interparental stress across multiple levels and domains of child functioning, including emotional, cognitive, coping, and physiological responding.

Further illustrating the operation of mediational paths, Path 2 in our model postulates that part of the relationship between interparental conflict and child maladjustment is mediated by parent-child dynamics, including specific child-rearing practices, parent-child relationship features (e.g., attachment), and coparenting relationship qualities. In further broadening the scope of the model, an array of

broader contextual characteristics, including child, familial, and extrafamilial attributes, are theorized to alter both direct and indirect pathways involving interparental conflict and child maladaptation in several ways. For example, as illustrated by Path 3 in the model, contextual characteristics may mediate the vulnerability of children exposed to high levels of interparental discord. Likewise, guided by risk and protective models in developmental psychopathology, Path 4 illustrates that associations between interparental conflict and child maladaptation may be moderated by contextual characteristics. For example, interparental relations are considered to assume different meanings depending on the balance of resources and risk in the family and ecological setting.

Fully integrating interparental models of psychopathology in a developmental framework also necessitates consideration of other developmental issues. Accordingly, Path 5 in the model highlights the significance of developmental issues in the study of interparental functioning, with the core assumption being that the impact of interparental discord may vary depending on several developmental parameters. First, the magnitude and type of vulnerability of children may depend on the timing and duration of the

conflict. For example, sensitive periods may be operating whereby environmental influences are particularly pronounced in specific developmental windows (e.g., Cicchetti, 1993). Likewise, in illustrating the significance of the duration of experiential histories of exposure to interparental process, the quality of subsequent change in child functioning may be constrained by prior organizational adaptations (Sroufe, Egeland, & Kreutzer, 1990; Waddington, 1957). Second, drawing from stage-salient models of developmental psychopathology, child adaptation to interparental conflict over time may be gauged by the ways children approach and resolve the unfolding series of developmental challenges that become particularly prominent during a given period of development (Cicchetti, 1993; Sroufe, 1979; Sroufe & Rutter, 1984). Third, from a developmental perspective, another important goal is to understand how the interplay among interparental conflict, contextual characteristics, and child response processes corresponds with children's developmental trajectories of psychopathology and resilience over time. Even though child maladaptive response patterns to family stress may mediate the risk of growing up in a discordant home, the concept of multifinality indicates that children who exhibit highly similar patterns of reactivity and coping may evidence different developmental trajectories. Therefore, a complete multivariate model of interparental conflict must incorporate developmental parameters of timing and duration of stressors, developmental periods, and developmental pathways.

DIRECT PATHWAYS AND PROCESSES IN MODELS OF INTERPARENTAL DISCORD

A primary aim of a process-oriented approach and, more broadly, developmental psychopathology, is to advance an understanding of the conceptual ordering of variables in direct paths between interparental conflict and the multiple levels of child functioning. A common strategy across different direct path models of interparental discord is to identify the specific processes and process relations in context that, over time, underlie what is classified diagnostically as normal development or psychopathology (see Path 1 in Figure 3.1). Originally distilled from models of developmental psychopathology (Cowan, Cowan, & Schulz, 1996), these theories draw distinctions among *risk factors*, *risk processes*, and *outcomes*. Risk factors in these models probabilistically increase child maladaptive outcomes. However, the operation of the risk is neither static nor instantaneous. Rather, repeated exposure to the risk factor results in the dynamic emergence of risk processes

characterized by regularity in child response patterns in specific contexts that, over time, intensify, broaden, and crystallize into symptomatology and psychopathology. Thus, the common aim across direct path models is to identify how interparental discord serves as a specific risk factor by engendering risk processes characterized by specific child response patterns that, in the long run, lay the foundation for negative outcomes (e.g., symptomatology, psychopathology, competence).

Direct Path Models of Interparental Discord

Despite adopting a common goal of distinguishing among risk factors, risk processes, and outcomes, various theories of interparental discord offer a diverse array of explanations for why interparental conflict is deleterious to child functioning. To illustrate the diversity in response processes addressed across theories, we provide a brief and selective review of the assumptions of some of the more established direct path models.

Social Learning Theory

Applications of social learning theory to the study of interparental discord have underscored how the child's responses are learned in the context of interparental interactions. Like the other direct path models, social learning theory hypothesizes that child exposure to interparental conflict tactics has direct effects on child functioning that cannot be accounted for by parenting or family processes. Observational learning or modeling is regarded as a primary process that organizes child responses (Bandura, 1973, 1983). In the context of interparental conflict, children are viewed as having opportunities to master new ways of engaging in aggressive behavior through vicariously observing adults engage in aggressive and hostile conflict tactics. Greater displays of hostility and aggression by children when exposed to interparental hostility are thought to emerge through multiple processes, including (1) precise imitation of specific hostile behaviors displayed by adults, (2) acquisition of generalized scripts or abstract rules for engaging in hostile behaviors, and (3) reduction of inhibitions about aggressing (Cox, Paley, & Harter, 2001; Emery, 1982; Margolin, Oliver, & Medina, 2001).

These main assumptions lead to a more precise articulation of the specific linkages among risk factors, risk processes, and outcomes. As illustrated in the first model in Figure 3.2, children are commonly hypothesized to display high levels of aggression and hostility with progressively greater exposure to bouts of interparental physical aggression, verbal hostility, and unvarnished anger dis-

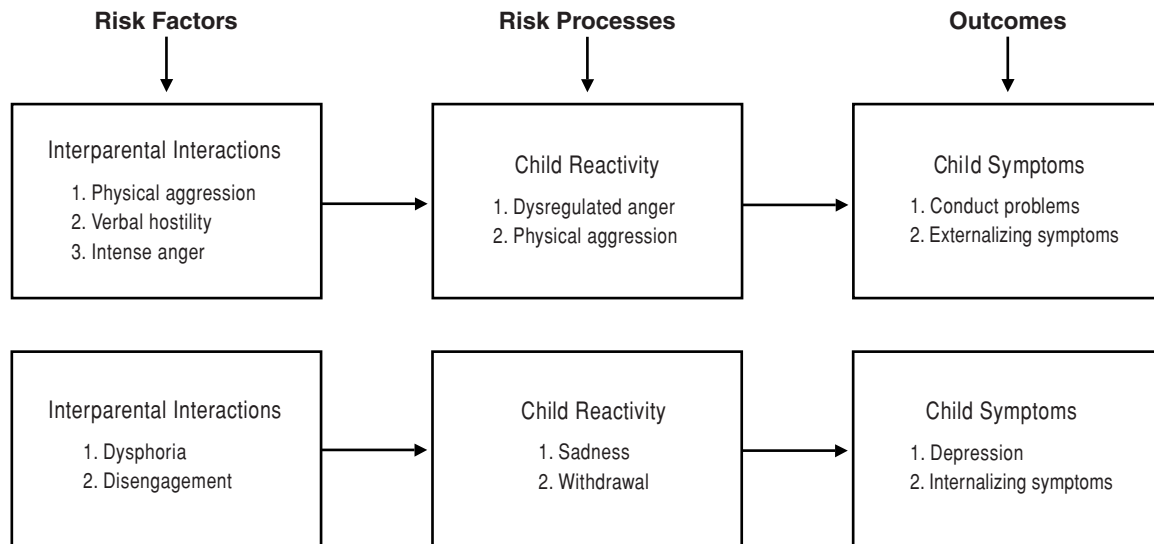

Figure 3.2 A social learning theory formulation of direct pathways and processes of interparental discord.

plays. In turn, these increasing tendencies to display aggression are proposed to intensify and broaden into conduct problems. Although the transmission of aggressive displays has received more attention in models of interparental discord, the potential value of social learning theory is not confined to explaining the operation of interparental discord in the genesis of conduct problems. For example, interparental discord can be expressed in multiple ways that include (but are not limited to) spousal disengagement and dysphoria. In illustrating this multiple pathways perspective, the second model in Figure 3.2 theorizes that interparental dysphoria or disengagement may specifically increase children's vulnerability to internalizing symptoms by fostering their vicarious displays of sadness and social withdrawal.

Emphasis on reinforcement contingencies in social learning theory has also generated hypotheses about additional developmental pathways to psychopathology. For example, in applying the negative reinforcement principles to the study of interparental conflict, Emery (1989) proposed a three-component model. First, interparental conflict is hypothesized to be an aversive event that produces distress in children. Second, children's dysregulated expressions of distress (e.g., aggression, temper tantrums) reduce their exposure to aversive interparental stimuli by distracting parents from engagement in ongoing conflicts. Third, misbehavior is more likely to be enacted by the child in subsequent conflicts because it reduces or eliminates the aversive stimulus (i.e., conflict). As this negative reinforcement process is repeated over time, children are proposed to show increasingly strong, persistent aversive

behaviors, which, in turn, pave the way for broader patterns of behavior problems.

Although social learning theory has been consistently invoked to explain associations between interparental conflict and child functioning (e.g., Crockenberg & Langrock, 2001a; Emery & O'Leary, 1982; Johnson & O'Leary, 1987), modeling explanations are typically provided post hoc. Studies have rarely been conducted for the explicit purpose of testing social learning processes, especially as they relate to proposed mediational pathways among risk factors (e.g., interparental aggression), risk processes (e.g., child aggressive reactions to conflict), and outcomes (e.g., child conduct problems). Thus, considerably more empirical precision is needed to sufficiently test hypotheses generated from social learning theory.

The Cognitive-Contextual Framework

Rooted in social-cognitive theories of interparental relations, the cognitive-contextual framework places particular emphasis on understanding how the cognitive dimensions of children's appraisals shape the impact of conflict on child adjustment (e.g., Grych & Fincham, 1990, 1993; Grych, Seid, & Fincham, 1992). Children are viewed as active agents who attempt to derive interpersonal meaning from the ways their parents manage conflict. However, in contrast to the primary focus of social learning theory on understanding the genesis of externalizing symptoms, the cognitive-contextual framework has been particularly useful in accounting for child vulnerability to internalizing symptoms. Two dimensions of child appraisals assume center stage in explaining why interparental conflict increases

child vulnerability to psychopathology. In the first process pathway, exposure to high levels of parental conflict may pose a risk to children's adjustment by heightening their perceptions of threat posed by conflicts. Perceived threat is specifically characterized by children's analyses of the threat that conflicts pose to their welfare and ability to successfully cope with conflict. In the early stages of this unfolding series of processes, children are thought to become increasingly more prone to perceive parental conflicts as threatening with repeated exposure to angry, hostile, and unresolved disputes between parents. Increasing appraisals of threat, in turn, are thought to predispose children to experience anxiety, dysphoria, and helplessness and, as a result, increase their risk for developing internalizing symptoms (Grych, Fincham, Jouriles, & McDonald, 2000).

Child attributions regarding the cause of the conflict is the second set of mechanisms that are presumed to account for why interparental conflict directly affects children's functioning. A primary thesis is that children exposed to angry, hostile, and unresolved conflicts are likely to assume the role of parental peacekeeper, arbitrator, and confidante. However, the child's involvement in the conflict is not likely to play a significant role in resolving the complex adult problems or the accompanying emotional strife. Thus, as children increasingly bear the formidable responsibility of reducing interparental and family discord, they may be especially prone to blaming themselves for the maintenance or escalation of interparental difficulties. Increasing feelings of guilt, shame, helplessness, and poor self-worth, which are regarded as affective outgrowths of this appraisal process, are proposed to develop into broader patterns of internalizing symptoms.

Studies examining the roles of children's perceived threat and self-blame have provided some support for the proposed mediational pathways. Grych, Fincham, and colleagues (2000) have reported that perceived threat and self-blame were consistent mediators of the relationship between interparental conflict and child symptoms in both community and risk (i.e., battered women's shelters) families. In accordance with the emphasis on the genesis of internalizing symptoms, the mediational paths accounted for children's individual differences in internalizing symptoms but not externalizing symptoms. Similar patterns of findings regarding the mediational role of child perceived threat and self-blame have been reported in other studies (e.g., Dadds, Atkinson, Turner, Blums, & Lendich, 1999; Kerig, 1998). However, more recent longitudinal analyses conducted by Grych, Harold, and Miles (2003) have yielded a more complex pattern of findings (also see Davies, Harold, Goeke-Morey, & Cummings, 2002). Con-

sistent with earlier findings, interparental conflict was associated with subsequent increases in child appraisals of threat and self-blame across 1 year. Child threat appraisals, in turn, were consistent concurrent predictors of changes in child internalizing symptomatology. However, unlike earlier studies, perceived blame was actually a predictor of child externalizing symptoms. Moreover, because interparental conflict was negligibly associated with child psychological maladjustment, the findings failed to support a mediator model. Instead, the findings provided support for another type of indirect effect whereby child appraisals were intervening (rather than mediating) mechanisms linking interparental conflict and child maladjustment.

Although empirical work on the cognitive-contextual framework has been heavily rooted in elucidating the role of children's social-cognitive mechanisms, the theory conceptualizes appraisals as part of a more complex pattern of unfolding processes across multiple domains and levels of child functioning (Grych & Cardoza-Fernandes, 2001; Grych & Fincham, 1990). Histories of exposure to destructive interparental conflict are specifically theorized to engender a variety of appraisals that are not fully captured by a focus on perceived threat and self-blame (e.g., efficacy expectations, expectancies about the course of conflict). Constellations of appraisals, in turn, are thought to engender negative emotionality. In the final part of this response process, the reciprocal interplay between appraisals and emotional arousal is conceptualized as prompting children to reduce emotional arousal in the proximal stressful context through emotion-focused (e.g., avoidance) and problem-focused (e.g., intervention in conflict) coping. Given the paucity of research on other components of the cognitive-contextual framework, examining social-cognitive appraisals in this broader organization of response processes is an important direction for future research (Grych & Cardoza-Fernandes, 2001).

The Emotional Security Theory

A main assumption of the emotional security theory is that preserving a sense of security is an important goal that organizes children's emotional experiences (e.g., fear), action tendencies (e.g., withdrawal, intervention), and appraisals of self and interpersonal relationships (e.g., internal representations of threat to the self). Although the child evaluates interpersonal contexts in relation to multiple goals, the emotional security hypothesis postulates that protection, safety, and security are among the most salient and important in the hierarchy of human goals. Rather than postulating that preserving a sense of security is relevant only to the parent-child attachment, the emotional security

theory hypothesizes that children also develop a sense of security in the context of the interparental relationship that is distinct in its substance, origins, and sequelae from attachment security. For example, children may evidence insecurity in the context of interparental relations but experience security in the mother-child or father-child attachment relationship.

Figure 3.3 illustrates the direct pathway prediction of the emotional security theory. The main thesis is that children's difficulties in preserving security in the interparental relationship partially mediates or explains the direct association between interparental conflict history and child vulnerability to adjustment problems. Path 1 illustrates the assumption that the threat associated with exposure to destructive interparental conflict is especially likely to sensitize children to concerns about the goal of preserving their security in subsequent contexts of interparental difficulties. Preserving emotional security, in turn, is conceptualized as a latent goal that regulates and is regulated by three observable classes of response processes: emotional reactivity, regulation of conflict exposure, and internal representations (see Path 2 in Figure 3.3). Thus, threats to the goal of security are posited to activate responding across the three classes of response processes, as reflected in greater emotional reactivity (i.e., proneness to prolonged and dysregulated experiences of fear, vigilance, and distress in the context of interparental problems), excessive regulation of conflict exposure (i.e., avoidance of and involvement in interparental problems),

and hostile internal representations of the consequences that interparental difficulties have for the welfare of the self and family (Davies & Cummings, 1994, 1998). Reflecting the bidirectional interplay between the goal and response processes, activation of three component processes is thought to serve the biological and evolutionary function of promoting the attainment of physical and psychological safety in the average expectable environment. Thus, emotional reactivity may be initially adaptive in emotionally tagging or highlighting the significance of potential threat present in high-conflict homes and in energizing children to quickly cope with impending adversity. Likewise, expending resources to intervene or avoid conflicts may be an effective way of preserving security by increasing the emotional or physical distance from threatening interparental events. Finally, child representations, which are geared toward processing the meaning of interparental conflict for family life, are thought to serve as radar systems for identifying interparental events that may proliferate to undermine the welfare of the self and family (Davies, Forman, Rasi, & Stevens, 2002; Davies, Harold, et al., 2002).

With repeated exposure to interparental conflict, a main premise is that the goal-corrected system of security becomes increasingly sensitized to subsequent conflict. Thus, experiential histories of interparental strife are specifically postulated to increase child insecurity, as manifested by high levels of emotional reactivity, regulation of conflict exposure, and hostile internal representations. Consistent

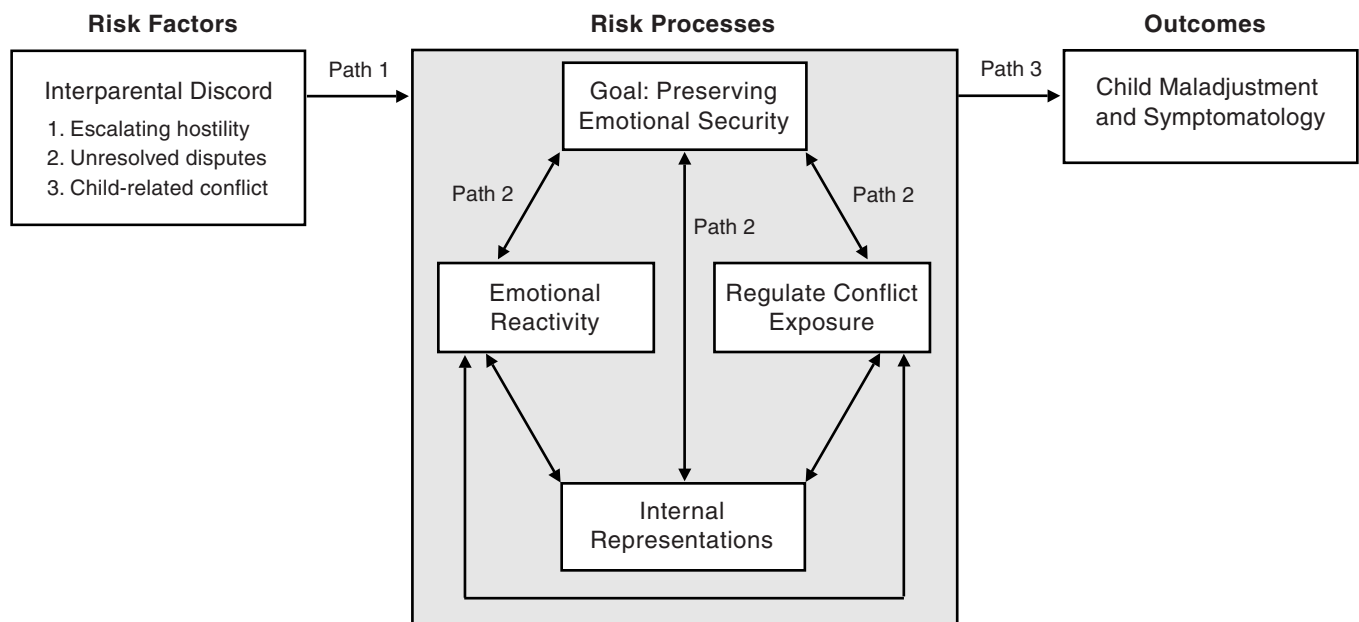

Figure 3.3 An emotional security formulation of the direct pathways and processes of interparental discord.

with these predictions, children exposed to high levels of interparental conflict exhibit high levels of emotional reactivity (e.g., fear, distress; Davies & Cummings, 1998; El-Sheikh, 1997; Garcia O'Hearn, Margolin, & John, 1997; Gordis, Margolin, & John, 1997), negative representations of interparental conflict (e.g., Davies & Cummings, 1998; Davies, Forman, et al., 2002; Davies, Harold, et al., 2002), and, at least in some cases, greater regulation of exposure to parental difficulties (e.g., Davies, Forman, et al., 2002; Garcia O'Hearn et al., 1997; Sandler, Tein, & West, 1994). In the second part of the mediational chain (see Path 3), the three classes of response processes in the emotional security system are hypothesized to increase child vulnerability to psychological symptoms. Although elevated concerns about security for children from high-conflict homes may hold adaptational value, the emotional security theory further postulates that these concerns may have maladaptive value for children's long-term functioning. For example, vigilance, distress, and preoccupation triggered by exposure to interparental difficulties are posited to lay the foundation for broader patterns of internalizing and externalizing symptoms. Likewise, prolonged operation of the emotional security system is theorized to require considerable expenditure of psychobiological resources thereby, depleting children of resources that are necessary to cope with and resolve other important developmental challenges and goals (Saarni, Mumme, & Campos, 1998; Thompson & Calkins, 1996). Consistent with these hypotheses, children's psychological symptoms have been predicted by their emotional reactivity, regulation of conflict exposure, and internal representations of marital relations (e.g., Davies & Cummings, 1998; Davies, Forman, et al., 2002; Davis, Hops, Alpert, & Sheeber, 1998; Harold & Conger, 1997).

Although identifying associations among interparental conflict history, child emotional security, and child adjustment is a prerequisite to testing mediational pathways, the final step requires demonstrating that emotional security accounts for a substantial portion of the variance in associations between interparental conflict history and child adjustment problems. The small corpus of studies directly addressing this association has yielded some support for this hypothesis. For example, Davies and Cummings (1998) reported that child emotional reactivity and negative representations in the context of parental conflict simulations partially accounted for the relationship between interparental conflict and child adjustment problems. In supporting the hypothesis that emotional insecurity is distinct from attachment security, emotional insecurity has also been shown to mediate the link between interparental con-

flict and child problems even after taking into account parenting and parent-child attachment security (Davies, Harold, et al., 2002).

Specific Emotions Theory

Congruent with emotional security theory, specific emotions theory is guided by the functionalist perspective and proposes that children's evaluations of and emotional reactivity to conflict, which are inextricably linked with goals, play a central role in explicating direct pathways between interparental conflict and child adjustment (Crockenberg & Langrock, 2001a, 2001b). However, whereas the emotional security hypothesis focuses specifically on the operation of security goals, specific emotions theory expands the conceptual boundaries in an attempt to incorporate multiple goals systems. Thus, according to specific emotions theory, children's appraisals and reactions develop in the context of any number of goals, both broad (e.g., security, affiliative) and specific (e.g., obtaining parental permission to engage in desirable activities; also see Jenkins, 2000, 2002). Children are specifically theorized to develop coherent ways of evaluating the meaning conflict has for the attainment of their goals from repeated experiences of interparental conflict events over time. In the unfolding series of processes, evaluations of the meaning of conflict in relation to specific goals result in specific emotional reactions. Consistent with the functionalist perspective (e.g., Saarni et al., 1998), child appraisals of the probability of successfully achieving or maintaining a valued goal in the context or aftermath of conflict organizes specific emotional experiences. Anger, with its function of marshaling psychological and biological resources to overcome obstacles and assert interpersonal dominance, is likely to develop when children evaluate a threatened or blocked goal as likely to be attainable. In contrast, sadness is associated with the conservation of intraorganismic resources and the elicitation of caregiving and support in interpersonal contexts. Accordingly, sadness is likely to emerge as a broader reaction pattern in contexts in which valued goals are repeatedly unattainable. Finally, fear and worry serve the function of energizing individuals to respond quickly to potential threat. Thus, contexts that pose a looming, but uncertain, threat to the preservation of goals are likely to trigger fear responses. Specific emotional responses to conflict, in turn, are thought to coalesce into broader patterns of adjustment and maladjustment. Proclivity to experience anger is hypothesized to trigger aggression and, in the process, portends subsequent externalizing symptoms, whereas withdrawal behaviors prompted by fearful responses are thought to engender broader patterns of internalizing symptoms.

Sadness is also proposed to increase child vulnerability to internalizing symptoms by fostering vegetative and withdrawal behaviors in the face of adversity. Finally, reflecting the interaction between specific emotional reactions to conflict, specific emotions theory suggests that angry responses that co-occur with fear are likely to inhibit aggressive responses and facilitate withdrawal behaviors and, more broadly, internalizing symptoms.

Given that specific emotions theory is in the early stages of development, tests of its derivative predictions have not been systematically undertaken (for exceptions, see Crockenberg & Forgays, 1996; Crockenberg & Langrock, 2001b). Incorporating the study of multiple goals and types of interplay between risk factors and processes is a strength of specific emotions theory. However, the accompanying limitation is that the broader explanatory scope of the model compromises its theoretical precision. Thus, further conceptual development and refinement will facilitate future empirical tests of the theory, particularly in more precisely articulating the interplay between interparental conflict histories and child appraisals and emotional reactivity.

For example, even though child appraisals and emotional reactivity were cast as mediators of interparental conflict in the initial theoretical exposition (Crockenberg & Langrock, 2001a), Crockenberg and Langrock (2001b) have subsequently proposed that identification of either a mediating or a moderating role of children's specific emotions would support a specific emotions theory. Likewise, broadening the explanatory power of the model by including multiple goal systems, each of which contains considerable complexity, also increases the challenge of precisely articulating how response processes (e.g., emotion reactivity, appraisals) function within the overall configuration of each goal system. From a developmental psychopathology perspective, it would also be useful to further articulate the pathways that link specific types of emotional reactions to the development of particular forms of psychological problems.

Summary

In summary, considerable progress has been made over the last 15 years in developing several theoretical accounts for why interparental conflict directly affects child functioning. These theoretical advances have specifically facilitated efforts to understand the multidimensional, dynamic function of risk factors and risk processes in direct path models.

In the next section, we expand on this theme by examining the value of specifying the nature of risk factors and

processes in developmental psychopathology models of interparental conflict.

The Operation of Interparental Risk and Compensatory Factors in Direct Path Models

Despite the fact that interparental conflict is often treated as a homogeneous construct, interparental conflict, in fact, varies widely in impact and on multiple dimensions of behavioral and emotional expression. Thus, given the emphasis of the developmental psychopathology perspective on delineating the role of context, a fundamental goal is to differentiate the dynamic implications for child development of multiple and specific forms of marital conflict. At the same time, the principle of equifinality in developmental psychopathology underscores that multiple and alternative forms of expression of marital conflict can have similar implications from the perspective of the children (Davies, Myers, Cummings, & Heindel, 1999). For example, multiple behaviors may have similar meanings from the children's perspective as representations of constructive or destructive conflict. Thus, goals at this level of analysis should include both differentiating the effects of specific expressions of conflict and identifying higher-order categories or organizational meanings of conflict behaviors.

A developmental psychopathology perspective places particular emphasis on considering the normal and abnormal together (Sroufe, 1990). Interparental discord is related to risk for psychopathology in both parents and children (E. M. Cummings & Davies, 1994a; Du Rocher Schudlich, Papp, & Cummings, 2004). Thus, in principle, some forms of interparental conflict may serve as risk factors that probabilistically increase risk of psychopathology. However, failing to consider the operation of interparental conflict in normal family functioning runs the risk of overpathologizing conflict environments. Marital conflict is a normal characteristic of marital relationships that can be regarded as essential to the daily conduct of marital relations. Disagreements or expressions of negative emotions over everyday matters are common occurrences in marital and family life. Children not only may adapt to marital discord, but some forms of conflict expressions may broadly predict greater psychological adjustment regardless of whether individuals experience risk (E. M. Cummings, Davies, & Campbell, 2000). Thus, over time, marital conflict may contribute to normal and abnormal developmental trajectories in children, although risk associated with marital conflict is probabilistic rather than certain (Sroufe, 1997).

Strategies for Identifying Interparental Risk and Compensatory Factors

Recognizing that interparental conflict can serve as either a risk or a compensatory factor is an important first step in advancing tests of direct path models. However, a remaining challenge is to empirically test which conflict tactics serve as risk or compensatory factors. Supporting the assumption that methodological diversity is the key to substantive vigor in developmental psychopathology (E. M. Cummings et al., 2000), several complementary strategies have proven to be valuable in delineating the developmental implications of specific conflict tactics. One methodological strategy, which can be characterized as a categorical risk design, takes advantage of experiments of nature to more precisely isolate specific patterns of child exposure to interparental conflict tactics (Cicchetti, 2003). In these designs (e.g., Fantuzzo et al., 1991; O'Brien, Margolin, John, & Krueger, 1991), inclusion and exclusion criteria are developed and implemented to identify groups of children who differ in their exposure to specific conflict tactics but are highly similar in sociodemographic characteristics and other family experiences. For example, Fantuzzo and colleagues compared the psychological adjustment of children in four groups: (1) home residents exposed to verbal interparental aggression, (2) home residents exposed to both verbal and physical interparental aggression, (3) shelter residents exposed to verbal and physical interparental aggression, and (4) a control group of home residents exposed to negligible levels of interparental aggression. By carefully selecting naturally occurring groups of children who differ in their exposure to a well-defined set of family stressors, this design disentangled the specific risk posed by the form of aggression and residence (i.e., homelessness) to children's adjustment from a larger constellation of covarying demographic conditions. Even though the categorical risk design has proven to be an excellent strategy for increasing the specificity of conflict assessments, like other designs, it does have its share of limitations.

Classifying groups of children based on their exposure to specific types of conflict tactics in categorical risk designs often involves reducing rich, continuous assessments of conflict into a more simple categorical variable based on arbitrary cut points. Although this practice is an appropriate step in addressing some research questions, the trade-off is a substantial loss of information and statistical power. For example, implementing an arbitrary cutoff on a continuous measure of interparental conflict (e.g., verbal aggression) may yield a group of children who exhibit considerable heterogeneity in their exposure to the specific

conflict tactic (e.g., moderate versus no exposure). Thus, categorical systems often fail to assess the full quantitative continuum of conflict risk (Seifer, 1995). Moreover, even if theory proposes qualitative shifts in the operation of a risk factor, specific categorical cut points may not correspond with the locus of the exponential change in the nature or magnitude of the conflict tactics.

To address these limitations, marital researchers complement clinical risk designs with retrospective field designs. The core objective of the continuous field design is to simultaneously examine the relative strength of continuous rather than arbitrary categorical assessments of conflict tactics predicting child functioning. For example, father-initiated violence in bouts of interparental conflict have been related to child behavior problems even after statistically controlling for general interparental discord (e.g., Fergusson & Horwood, 1998; McDonald, Jouriles, Norwood, Ware, & Ezell, 2000; Yates, Dodds, Sroufe, & Egeland, 2003). However, despite maximizing the use of rich data and statistical power, these designs rely heavily on the recall and report of interpartner conflict tactics and child functioning over relatively lengthy periods of time (e.g., months or years) by family members. Without the use of other approaches to complement this design, the validity of findings may be compromised by memory or response bias errors and inherent limitations of capturing precise (as opposed to global) dimensions of interparental and child functioning. Thus, retrospective field designs have been limited largely to the assessment of broad and easily discernable dimensions of child (e.g., conduct problems) and interparental (e.g., global indices of conflict frequency or violence) functioning (E. M. Cummings et al., 2000).

To address these methodological pitfalls, researchers have developed daily record or diary procedures (e.g., E. M. Cummings, Zahn-Waxler, & Radke-Yarrow, 1981, 1984; Garcia O'Hearn et al., 1997). Because diary records place less demand on memory and recall than questionnaires, these reports may provide more accurate assessments of specific interparental and child behaviors rather than global impressions. New methods of training mothers and fathers to complete home diaries and procedures for testing reliability and correspondence among parents as coders have yielded more psychometrically sound methods for recording interparental conflict events in the home (see E. M. Cummings, Goeke-Morey, & Dukewich, 2001; E. M. Cummings, Goeke-Morey, & Papp, 2003a). Moreover, daily records can now be completed in checklist rather than narrative format (e.g., E. M. Cummings, Goeke-Morey, & Papp, 2003b; Garcia O'Hearn et al., 1997), thereby decreasing demands on parents and increasing the

accessibility of the methodology to a broader sampling of adults (e.g., adults with limited verbal skills). Thus, by providing assessments of specific spousal and child behaviors in the context of interparental conflict, daily record procedures have the potential to yield important findings on multiple pathways between interparental conflict tactics and child reactivity and coping. Corresponding progress has been made in examining how observer assessments of specific conflict tactics in interparental interactions in the laboratory are associated with particular dimensions of child functioning (e.g., Katz & Gottman, 1993; Katz & Woodin, 2002).

Another useful strategy for explicating the effects of specific conflict tactics on child risk processes consists of using laboratory simulations of interadult conflict. Precision and control afforded by analogue designs are especially useful in examining process associations between interparental conflict dimensions and child responses. For example, full experimental designs, which manipulate specific conflict tactics in the controlled setting of the laboratory and assess their effects on children, provides a useful way of disentangling interparental conflict tactics from the larger matrix of covarying family and interpersonal processes (E. M. Cummings & Davies, 1994a). As a result, more confident conclusions can be made about the direct effects of specific conflict tactics on child functioning (e.g., E. M. Cummings, Vogel, Cummings, & El-Sheikh, 1989; Davies, Myers, et al., 1999; El-Sheikh & Cheskes, 1995; Grych & Fincham, 1993). One ongoing research direction involves identifying higher-order categories or organizational meanings of conflict behaviors from the child's perspective. For example, Goeke-Morey, Cummings, Harold, and Shelton (2003) classified 11- and 12-year-old Welsh children's emotional responses to analogue presentations of marital conflict vignettes into destructive and constructive dimensions based on the balance and organization of children's positive and negative emotional reactivity to the vignettes. Analogue or experimental designs are also proving to be useful in testing the relative viability of predictions about the effects of specific conflict tactics derived from complementary theoretical frameworks. For example, Davies, Harold, and colleagues (2002) examined whether patterns of relationships between simulations of specific conflict tactics and children's negative affect were more consistent with predictions derived from the emotional security theory or social learning theory.

A common limitation of the experimental design is that ecological validity is compromised to maximize internal validity. However, quasi-experimental designs, which are characterized as hybrids of experimental and naturalistic

designs, may provide a way of preserving some balance between internal and ecological validity. For example, several theories of interparental conflict (e.g., emotional security theory, cognitive-contextual framework) have postulated that histories of exposure to destructive interparental conflict sensitize children to subsequent conflict, as evidenced by heightened emotional distress, maladaptive coping, and negative appraisals and representations. Although field designs have demonstrated that children from high-conflict homes react more negatively to naturalistic conflicts in the home (e.g., Garcia O'Hearn et al., 1997), they cannot solely determine whether the negative emotional reactivity is due to the sensitizing effects of distal conflict histories or the proximal conflict context. Analogue studies, by contrast, can better isolate the effects of conflict history on children's subsequent responses to marital conflict. For example, in one analogue design (Davies, Myers, et al., 1999), children were randomly assigned to view videotapes of the same adult couple engaged in either four hostile, unresolved conflicts (i.e., destructive) or four mild, resolved conflicts (i.e., constructive) to simulate child exposure to conflict histories. Following this manipulation of conflict history, children were interviewed about their responses to a standard conflict between the same couple. Supporting the sensitization hypothesis, children who witnessed destructive conflict histories generally reported greater negative responding to the standard adult conflict than children exposed to constructive conflict histories. However, because they can ascertain only whether exposure to distal histories of adult conflict *can* cause sensitization in children, it is still unclear whether lengthier histories of conflict between actual parents actually cause sensitization (e.g., Davies, Myers, et al., 1999; El-Sheikh, Cummings, & Reiter, 1996). Thus, to preserve some degree of ecological validity, researchers have obtained reports of actual interparental conflict history from family members. In the same design, some level of experimental control and internal validity is achieved by assessing children's responses to standardized conflict simulations in the laboratory (e.g., Davies, Cummings, & Winter, 2004; El-Sheikh, 1997; Grych, 1998; O'Brien, Bahadur, Gee, Balto, & Erber, 1997).

Interparental Risk Factors in Direct Path Models

In direct path models, *risk* factors are defined as specific characteristics of interparental difficulties that probabilistically increase maladaptive patterns of child reactivity to interparental stress, which, in turn, ultimately amplify child risk for psychopathology. Distinctions are drawn between child reactivity and child psychopathology because, in a multiple-levels-of-analysis perspective, specific types

of interparental risk may be associated with greater psychopathology without directly altering child response processes. For example, child maladjustment has been associated with specific types of interparental difficulties, including greater interspousal violence (Dumas, Margolin, & John, 1994; Fantuzzo et al., 1991; Jouriles, Murphy, & O'Leary, 1989), verbal aggression (Johnston, Gonzales, & Campbell, 1987), disengagement (Jenkins & Smith, 1991; Katz & Gottman, 1997; Katz & Woodin, 2002; Kerig, 1996), dysphoria (Du Rocher Schudlich & Cummings, 2003), and child-related conflict (Jouriles, Murphy, et al., 1991; Snyder, Klein, Gdowski, Faulstich, & LaCombe, 1988). Although these forms of interparental conflict are defined as general risk factors because they are associated with greater maladjustment, they are not regarded as specific risk factors in direct path models unless they increase risk for maladjustment by directly engendering maladaptive patterns of responding to interparental stress. Put another way, "specific" risk factors are defined as interparental conflict tactics that have a direct, deleterious impact on child functioning, whereas the term "general" risk factors is reserved for conflict tactics that influence child functioning indirectly through their associations with family functioning.

For some conflict tactics, studies demonstrate remarkable consistency in the classification of the same conflict tactics as serving as both a general and a specific risk factor. Thus, in addition to its role in the genesis of adjustment problems, exposure to interparental violence has also been associated with subsequent reaction patterns to conflict that are thought to lay the foundation for later psychological problems (Kitzmann, Gaylord, Holt, & Kenny, 2003). Specific reaction patterns that have been identified as candidates for mediating direct paths involving interparental violence include greater negative emotional reactivity, maladaptive coping responses, and hostile representations in the face of conflict (J. S. Cummings, Pellegrini, Notarius, & Cummings, 1989; Grych, 1998; Grych, Wachsmuth-Schlafer, & Klockow, 2002; O'Brien & Bahadur, 1998).

For many other interparental risk factors, it is still too early to determine if they play a unique role in increasing vulnerability to child problems by directly altering children's adaptational capacities and patterns. For example, child-related disagreements are associated with adjustment problems even after statistically controlling for general interparental discord (e.g., Jouriles, Murphy, et al., 1991; Snyder et al., 1988). However, the sparse research addressing the specificity of associations between child exposure to child-related conflicts between parents and their maladaptive reaction patterns has yielded inconsistent findings

(e.g., Davies, Myers, & Cummings, 1996; Grych, 1998; Grych & Fincham, 1993). For example, a recent diary study indicated that children's increased aggression in response to conflicts about child-related themes in the home and conflicts about other personal, family themes had similar effects, so it is unclear that the child-related element of discussions was critical to elevated maladaptive responding (E. M. Cummings, Goeke-Morey, & Papp, 2004). Similarly, growing up in a home characterized by interparental hostile disengagement has been associated with more child psychological problems than exposure to interparental hostility alone (Katz & Woodin, 2002). However, little is known about whether disengagement between parents increases child vulnerability by taking a direct toll on children's coping and reaction patterns. Therefore, a plausible alternative hypothesis is that many of these conflict tactics may be associated with child problems through their association with family disturbances such as parenting difficulties, coparenting problems, or family-level adversity (Cox, Paley, Burchinal, & Payne, 1999; Katz & Woodin, 2002). Thus, identifying conflict tactics that operate as specific risk factors in direct path models will require more direct tests of mediational pathways between interparental conflict dimensions, children's reactivity to interparental conflict, and children's maladjustment.

Interparental Compensatory and Protective Factors in Direct Path Models

Conceptualizations of resilience and adjustment in developmental psychopathology can provide useful frameworks for more precisely clarifying how interparental conflict characteristics may operate to promote adjustment (Luthar, 1993; Luthar & Cicchetti, 2000; Luthar, Cicchetti, & Becker, 2000; Masten, Best, & Garmezy, 1990). Interpreted in these conceptualizations, constructive conflict behaviors can be usefully characterized as compensatory or protective factors in the development of psychopathology. Compensatory factors are defined as interparental conflict tactics that are broadly associated with heightened well-being in children, regardless of whether they face considerable adversity or risk, whereas protective factors are characterized by interparental conflict factors that reduce or offset risk in the face of substantial adversity.

Unfortunately, little is known about the dimensions of interparental conflict that may operate as protective or compensatory factors in children's development. Part of the knowledge gap can be attributed to the paucity of research on the constructive nature of conflict tactics. However, in issuing a call for more research in this area, we recommend that researchers use greater precision in identi-

fying the multitude of roles that a given conflict tactic might assume as a constructive factor in the lives of children. For example, a series of analogue studies have indicated that children's distress and negative cognitions diminish significantly in response to adult conflict as the degree of interadult resolution and subsequent positivity increases (e.g., E. M. Cummings, Ballard, El-Sheikh, & Lake, 1991; Davies et al., 1996). Parent reports of conflict resolution in the home have also been consistently associated with lower levels of children's internalizing and externalizing symptoms (e.g., Kerig, 1996). An important next step is to ascertain whether these constructive parameters of the interparental conflict process actually serve as compensatory or protective factors.

Furthermore, given that child adjustment is conceptualized as entailing multiple layers and dimensions in developmental psychopathology, factors identified as promising candidates for compensatory or protective effects may operate differently across different levels or domains of functioning. Thus, it will be imperative to identify the scope of the compensatory or protective effects of constructive forms of conflict. Do these conflict characteristics have compensatory or protective effects that are broadly applicable to different domains and levels of child functioning? Or, alternatively, are the salubrious effects of the conflict dimensions limited to specific dimensions of child functioning? Addressing these questions will help to advance tests of direct path models by examining whether conflict resolution or other constructive conflict parameters are associated with lower levels of psychological symptoms by directly decreasing maladaptive coping patterns or amplifying adaptive coping patterns.

The Operation of Risk Processes in Direct Path Models

Consistent with the conceptualization of pluralism in etiological pathways of interparental conflict, our previous review and analysis of the direct path theories provides evidence for the notion that multiple child risk processes mediate exposure to interparental conflict. For example, children from high-conflict homes exhibit greater distress, fear, and vigilance in response to parental conflicts and conflict simulations (e.g., Davies & Cummings, 1998; Davies, Harold, et al., 2002; El-Sheikh, 1997; Garcia O'Hearn et al., 1997; Gordis et al., 1997). Dimensions of negative emotionality in response to conflict have been associated, in turn, with greater risk for psychological problems (e.g., Davies & Cummings, 1998; Davis et al., 1998). Similarly, child negative cognitions or appraisals of the

psychosocial consequences of interparental difficulties have been identified as mediators of interparental conflict in both concurrent and prospective models of child maladjustment (e.g., Grych, Fincham, et al., 2000; Grych et al., 2003). Other studies have also found that destructive interparental conflict is associated with specific types of coping and regulatory patterns characterized by greater avoidance and involvement in family stress (e.g., Davies, Forman, et al., 2002; Garcia O'Hearn et al., 1997; Sandler et al., 1994). In turn, some studies have identified associations between coping and regulatory patterns like avoidance and involvement in family difficulties and child psychological problems (e.g., Gordis et al., 1997).

Emphasis on distinguishing between adaptive and maladaptive functioning in developmental psychopathology raises a broader research question: Why would children from high-conflict homes exhibit high levels of negative affect, hostile cognitive appraisals and expectancies, and coping and regulatory difficulties? In other words, why would children become more rather than less sensitive to conflict with repeated exposure, especially given that high levels of reactivity to conflict are unpleasant and may jeopardize child functioning in the long run? According to the contextual and organizational principles of developmental psychopathology (E. M. Cummings et al., 2000), the adaptational function of risk processes may vary across different contexts. Thus, even though heightened emotional reactivity and negative appraisals may increase child risk for psychopathology in the long run, these risk processes may actually have adaptational value in the context of high-conflict homes. For example, theories guided by the functionalist perspective highlight the adaptive value of affect in facilitating the achievement of significant psychological goals (Crockenberg & Langrock, 2001a; Davies, Harold, et al., 2002; Saarni et al., 1998; Thompson & Calkins, 1996). Moreover, in accordance with transactional models of developmental psychopathology (Sameroff, 1995), the specific regulatory strategy adopted by children largely hinges on specific transactions and feedback loops between the children and familial contexts. The emotional security theory specifically maintains that only regulatory strategies that have successful track records of preserving security will be sustained in future contexts. For example, children facing severe family adversity (e.g., maltreatment, domestic violence) may be especially likely to mask their distress in response to interparental conflict as a way of reducing their salience as targets of hostility by distressed, violence-prone adults (Shipman, Zeman, Penza, & Champion, 2000). Likewise, in drawing on social learning theory, Emery (1989) postulated that feedback loops and transactions between the

children and families culminate in higher levels of child involvement in interparental discord.

Diversity in the Operation of Risk Processes in Direct Path Models

Although a number of child responses have been identified as possible risk processes in direct path models of interparental conflict, different response processes do not necessarily carry the burden of interparental conflict in the same way. Accordingly, a key task is to further explicate the differential roles of specific response processes in the developmental psychopathology of angry home environments. For example, emotional distress and negative expectancies in the face of interparental difficulties have been shown to be robust mediators in associations between interparental conflict and child adjustment problems (Davies, Harold et al., 2002; Grych et al., 2003). In contrast, analyses of links between forms of interparental conflict, child regulatory or coping patterns (i.e., avoidance, involvement), and child maladjustment have yielded weak to modest support for mediational models (J. S. Cummings et al., 1989; Davies, Forman, et al., 2002; Jenkins, Smith, & Graham, 1989).

In further distinguishing among forms of child responding, researchers have suggested that the mixed support for the mediating role of involvement and avoidance may result from the failure to disaggregate the multidimensional nature of the constructs. For example, the emotional security theory postulates that the quality and substance of the regulatory strategy, rather than the mere presence, best captures emotional security and its long-term adaptational implications. Prolonged attempts to intervene that require considerable emotional and psychological investment or risk are theorized to reflect substantial difficulties restoring emotional security and lay the foundation for the development of psychopathology (Davies, 2002). Similarly, whereas brief and mild patterns of avoidance (e.g., distracting oneself through play) are postulated to reflect successful restoration of security, reflexive or dysregulated avoidance strategies (e.g., freezing, hastily fleeing the room) are predicted to signify considerable difficulties preserving security and may serve as precursors to later psychological problems. Similar progress has been made in identifying the specific roles of different types of child emotional reactions in models of interparental conflict (e.g., Crockenberg & Langrock, 2001a, 2001b; Davies, Harold, et al., 2002).

The paucity of empirical attention devoted to other indices of child reactivity has further contributed to the chal-

lenges of identifying variations in the mediational role of different risk processes. Progress in understanding the psychophysiological functioning of children from angry home environments has been particularly slow. However, emerging conceptual frameworks can provide useful conceptual guides in generating hypotheses. Reflecting a multilevel conceptualization of child functioning, useful distinctions have been drawn among different biological systems, including sympathetic-adrenomedullary (SAM) reactivity, hypothalamic-pituitary-adrenocortical (HPA) reactivity, and serotonergic functioning (see Repetti, Taylor, & Seeman, 2002). Building on the concept of allostatic load (e.g., McEwen, 1998; McEwen & Stellar, 1993), Repetti and colleagues specifically postulated that exposure to forms of family adversity lead to dysregulation in children's HPA, SAM, and serotonergic functioning over time that are manifested phenotypically in physical, neuropsychological, and psychological problems. Although noteworthy strides have been made in understanding linkages between forms of family adversity (e.g., maltreatment, attachment insecurity) and specific types of neurobiological dysregulation manifested in cardiovascular, brain electrical, and adrenocortical activity (Cicchetti, 2002; Repetti et al., 2002), the literature has lagged behind identifying the neurobiological and neuropsychological correlates of interparental conflict exposure. Moreover, the few studies addressing psychophysiological activity in models of interparental conflict, which have primarily focused on cardiovascular activity as a marker of SAM functioning, have yielded complex results (e.g., Ballard, Cummings, & Larkin, 1993; El-Sheikh, 1994; El-Sheikh, Harger, & Whitson, 2001; Katz & Gottman, 1997). For example, rather than serving as a mediator in associations between interparental conflict and child adjustment problems, as the allostatic load hypothesis predicts, some indices of cardiovascular activity (e.g., high basal vagal tone and vagal tone suppression) may act as moderators that protect or exacerbate the vulnerability of children exposed to high levels of conflict (see Katz & Gottman, 1997; El-Sheikh et al., 2001).

Although the operation of any given risk process has commonly been examined in isolation from the other risk processes, studies are beginning to make headway in understanding the relative role of multiple mechanisms in pathways between interparental conflict history and child adjustment problems. For example, tests of multiple appraisal processes in single statistical models designed to examine the cognitive-contextual framework indicated that the relative power of children's perceived threat and self-blame in models of interparental conflict varied depending on the type of psychological problem. Specifically, the

findings indicated that perceived threat was a key mechanism linking interparental conflict to child internalizing symptoms, whereas interparental conflict was indirectly associated with child externalizing symptoms through its association with high levels of self-blame (Grych et al., 2003). Likewise, researchers are in the early stages of testing the relative empirical fit of theoretically guided models in relation to other plausible conceptual models. For example, in testing the relative roles of child processes derived from the emotional security and cognitive-contextual theories, Davies, Harold, and colleagues (2002) reported that emotional security and appraisals of threat and self-blame each played unique, mutually informative roles in understanding pathways between interparental conflict exposure and child adjustment problems.

The Interplay among Risk Processes in Direct Path Models

The most common approach to delineating pathways between interparental conflict, child response processes, and child adjustment has been to dissect and analyze each specific form of child reactivity to interparental conflict in isolation from the larger constellation of children's reaction patterns. However, this approach may not fully capture the function of child response processes in direct path models. According to the organizational perspective in developmental psychopathology (Cicchetti & Cohen, 1995), any single form of child responding gains meaning in the context of the larger organization of child responding across multiple domains and levels of functioning. Therefore, relying on methods of disaggregating and isolating the study of a single response pattern may obscure an accurate analysis of the meaning of any single response domain within the larger profile of children's behavioral, affective, cognitive, and physiological reactivity to conflict.

Two classes of analytic approaches have proven to be particularly valuable tools in empirically capturing higher-order patterns of child reactivity to conflict. Variable-based approaches, which examine variables and their interrelations as the main conceptual and analytic units, have been successfully used in explicating the interactive interplay between multiple response domains. For example, guided by gender socialization theory, Crockenberg and Langrock (2001b) proposed that girls' angry reactions to interparental conflict have different implications for their psychological adjustment depending on whether they experience co-occurring fear. Supporting this hypothesis, post hoc plotting of a significant interaction between anger and fear indicated that angry reactions to conflict were especially likely to predict girls' internalizing symptoms when

they also exhibited fear in response conflict. However, variable-based models do have their share of limitations, especially in the statistical constraints of obtaining a stable solution if the synergistic interplay among any more than two or three variables is examined.

To remedy this limitation, researchers are increasingly utilizing person-based approaches to capturing higher-order patterns of child responding. Because the person or child is the primary conceptual and analytic unit of analysis, the core objective of the person-based designs is to synthesize and integrate the study of child responding within the holistic organization of children's emotional, behavioral, cognitive, and physiological responses to interparental difficulties. The emotional security theory proposes that there is considerable heterogeneity across children in the strategies they use to attain and preserve a sense of security in interparental contexts. Thus, some children may express difficulties in attaining security by exhibiting overt distress and avoidance, whereas other children who are having difficulties preserving security may intervene in conflicts. Moreover, in the conceptualization of emotional security as a dynamic, nonlinear control system, the meaning of morphologically identical responses to conflict (e.g., low distress) cannot be deciphered unless they are examined in relation to the larger constellation of children's responses. For example, in the context of high levels of overt emotional reactivity and excessive regulation of conflict exposure, low levels of self-reported distress may reflect an insecure strategy of suppressing subjective threat. Alternatively, if low subjective distress occurs in the context of well-regulated concern and low levels of involvement and avoidance, it may be regarded as part of a secure pattern of coping with conflict.

One approach utilized by Cummings and colleagues is to classify children into different groups based on their holistic pattern of responding to interadult anger across multiple response domains, including social and emotional behavior, self-reported emotional and cognitive reactions, and physiological functioning (E. M. Cummings, 1987; El-Sheikh, Cummings, & Goetsch, 1989). This classification process yielded three distinct higher-order response patterns: (1) concerned children, who exhibited well-regulated bouts of distress and signs of empathy in response to anger; (2) ambivalent children, who experienced high levels of emotional arousal typified by high levels of positive and negative affect; and (3) unresponsive children, who reported feeling elevated anger despite showing no overt signs of negative affect. Whereas concerned patterns of responding have been hypothesized to evolve from warm, supportive family relationships and, in

turn, set the stage for competent developmental trajectories, ambivalent or unresponsive profiles of responding were thought to result from exposure to chronic family adversity and increase child vulnerability to psychopathology. Partly supporting this hypothesis, Maughan and Cicchetti (2002) recently reported that the pathway between histories of maltreatment and child psychological symptoms was partially mediated by children's ambivalent response patterns to background anger.

In developing a pattern-based reformulation of the emotional security theory, Davies and Forman (2002) hypothesized that there were four primary styles of child emotional security in the context of parental conflict: secure, insecure-preoccupied, insecure-dismissing, and insecure-masking. *Secure* children, who were hypothesized to have confidence in their parents to manage disputes in a way that maintains family harmony, were postulated to exhibit well-regulated concern. The confidence of secure children was specifically theorized to evolve, in part, from witnessing well-managed parental disputes in the context of warm, cohesive interparental and family relationships and, in turn, set the stage for more healthy developmental outcomes. *Preoccupied* children were proposed to exhibit high levels of vigilance, anxiety, and involvement across behavioral and subjective indices of responding. This pattern, which was proposed to lay the foundation for negative self-perceptions and internalizing symptoms, was hypothesized to evolve from interparental and family processes that further draw children into interparental difficulties. *Dismissing* children, who were specifically posited to downplay the conscious experiences of threat in the interparental relationship, were hypothesized to exhibit high levels of overt distress but low levels of subjective distress and negative representations (also see Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993). Downplaying the significance of interparental conflict was further hypothesized to develop in the context of disengaged interparental relations, and, in turn, breed greater externalizing symptoms. In drawing on adversity models in developmental psychopathology (e.g., Shipman et al., 2000), *masking* children were postulated to inhibit overt expressions of high levels of subjective distress in an effort to limit their salience as targets of angry, violent, or dysregulated adults. Although masking may be regarded as adaptive for children exposed to imminent threats to their welfare (e.g., interparental violence), this pattern was postulated to increase children's vulnerability to psychopathology in the long run. Initial empirical tests have provided some promising support for

many of these predictions (see Davies & Forman, 2002, for more details).

INDIRECT PATHWAYS AND PROCESSES IN MODELS OF INTERPARENTAL DISCORD

Reflecting the multiplicity of pathways among risk factors, processes, and outcomes, Path 2 in Figure 3.1 on page 89 illustrates that interparental discord can increase child risk for maladaptive coping and, eventually, maladjustment indirectly through its association with disruptions in parent-child relationship dynamics. Although indirect effects models share the common assumption that family and contextual disturbances mediate the link between interparental conflict and child adjustment problems, models vary widely in the strength ascribed to the mediational pathways. Strong models of indirect paths, which make more assumptions about the power of contextual processes, postulate that parent-child relationship disturbances provide a complete explanation for why interparental discord is related to child adjustment (e.g., Erel, Margolin, & John, 1998; Fauber, Forehand, Thomas, & Wiersen, 1990; Patterson, DeBaryshe, & Ramsey, 1989). Thus, according to these reductionist conceptualizations, interparental conflict is only indirectly associated with child psychopathology through its covariation with parent-child relationship processes. However, running counter to strong models, accumulating evidence supports the notion that interparental conflict is directly associated with children's reactivity to conflict and adjustment problems even in the context of parenting disturbances (e.g., Davies, Harold, et al., 2002; Emery, Fincham, & Cummings, 1992; Frosch & Mangelsdorf, 2001; Webster-Stratton & Hammond, 1999). Thus, at least at this early stage of research, weak models of indirect effects, which relax claims about the magnitude of indirect pathways, appear to provide a better representation of research findings. Weak versions of indirect path models specifically embrace the assumption of plurality and diversity in developmental pathways by postulating that parenting disturbances only partially explain the risk posed by interparental discord to child maladjustment. Consistent with Path 2 in Figure 3.1, the following discussion is organized around the specific operation of parent-child dynamics as mediators in relations between interparental difficulties and child maladaptive coping and psychopathology. Three properties of the parent-child subsystem have received the most conceptual attention in indirect models of interparental and child functioning: (1) parenting or

child-rearing practices, (2) parent-child relationship quality, and (3) coparenting relations.

Parenting Practices

Predictions regarding the mediating role of parenting in models of interparental conflict have commonly been rooted in the integration of the spillover hypothesis (e.g., Erel & Burman, 1995; Floyd, Gilliom, & Costigan, 1998) and socialization models of parenting (Baumrind, 1971; Maccoby & Martin, 1983). In addressing the first link in the indirect path model of parenting, the spillover hypothesis specifically posits that parental anguish, indifference, and antipathy originally stemming from the unresolved spousal disputes is carried over into the parental interactions with children. Preoccupation, fatigue, and negative affect emanating from marital conflict is specifically thought to engender (1) poor behavioral management techniques reflected in lax monitoring and inconsistent or harsh discipline, (2) greater psychological control, characterized by efforts to control the child through manipulation and exploitation of the parent-child bond (e.g., love withdrawal, guilt induction), and (3) emotional unavailability, as evidenced by diminished responsiveness, sensitivity, and warmth. These specific types of parenting difficulties, in turn, are theorized to increase children's risk for psychopathology in socialization models of parenting.

Consistent empirical support for these indirect pathways is evident in the literature. Experimental, longitudinal, and sequential analyses have shown that disruptions in parenting increase over minutes, days, and months following interparental conflicts (e.g., Almeida, Wethington, & Chandler, 1999; Christensen & Margolin, 1988; Davies, Sturge-Apple, & Cummings, 2004; Jouriles & Farris, 1992; Kitzmann, 2000; Mahoney, Boggio, & Jouriles, 1996). Likewise, parental emotional unavailability, poor discipline and monitoring, and psychological control have been found to at least partially mediate the association between interparental conflict and child adjustment (e.g., Erel et al., 1998; Fauber et al., 1990; Gonzales, Pitts, Hill, & Roosa, 2000; Harold, Fincham, Osborne, & Conger, 1997; Webster-Stratton & Hammond, 1999).

Even in the face of ample empirical support for the mediational role of parenting, the nature of the interplay between marital conflict and parenting practices is not well understood. Little is known about whether the relative strength of indirect pathways varies across different parenting dimensions. It is plausible that some types of parenting practices may be particularly robust mediators of

marital conflict, whereas others may hold little or no power as explanatory processes. Supporting this possibility, the emphasis on affective processes in the spillover hypothesis and the emotional security theory suggests that parenting processes capturing emotional expressiveness in parenting are particularly potent mechanisms in indirect pathways of marital conflict (Davies & Cummings, 1994; Grych, 2002; Margolin et al., 2001).

Questions about how and why specific parenting practices exert their effects as mediators also remain largely unanswered. Developing a more formal and broader model that systematically integrates theories of parenting and marital conflict might provide a useful heuristic for advancing this next generation of research questions and hypotheses. In addressing the first link in the indirect path model of parenting, theoretical perspectives on marriage and parenting place differential emphasis on specific processes that accompany or result from interparental conflict and subsequently disrupt parenting (Sturge-Apple, Davies, & Cummings, *in press*). Although relationship perturbations, coping processes, negative affect, and personality attributes have been variously discussed as possible mechanisms, little attention has been devoted to developing precise conceptual and operational definitions of these hypotheses and simultaneously testing the relative merits of different mediating mechanisms (see Grych, 2002). Even testing processes within a specific conceptualization is likely to be challenging. For example, testing predictions derived from the spillover hypothesis will require increasingly complex perspectives on the affective processes by which interparental problems affect parenting. For example, the three-component affective model of parenting developed by Dix (1991) reveals that negative affect, in itself, may undermine parenting through multiple, distinct pathways, including (1) amplification of negative appraisals and attributions of child behavior, (2) constriction of attentional resources devoted to child-rearing activities, and (3) disruption of problem-solving abilities and facilitation of reflexive, dysregulated response patterns. By the same token, identifying the processes that account for why parenting problems in high-conflict homes increase child vulnerability to psychological difficulties would further the next generation of research. It is likely that exposure to various parenting difficulties may set in motion multiple processes within children (e.g., affective-motivational, social learning, social information processing) that ultimately serve as more proximal causes of their psychopathology (E. M. Cummings et al., 2000). Thus, evolving child response and

coping patterns in parent-child and family contexts may help to explain why parenting processes mediate associations between marital conflict and child maladjustment (see the next section for a specific illustration).

At an even broader level, the joint influence of marital conflict and parenting practices may not only be manifested in patterns of mediation. Family systems theory underscores that properties of any family subsystem (e.g., parent-child subsystem) may regulate properties of another family subsystem (e.g., interparental subsystem) in nonlinear ways. For example, to maintain homeostasis in the face of growing perturbations in the interparental subsystem, some parents may successfully attempt to offset child vulnerability to interparental adversity by becoming more invested in supporting the child and managing their own behavior. Thus, it is possible that some parenting practices may actually protect or buffer children from the deleterious effects of interparental problems. Alternatively, some parents who are experiencing distress in their relationships with their partner may attempt to fulfill lingering intimacy needs in the parent-child relationship through triangulation processes (e.g., Cox et al., 2001; Grych, 2002). If this presupposition is correct, it is possible that overly involved or enmeshed parenting patterns may actually potentiate or amplify the psychological burdens that children must shoulder in high-conflict homes. Although these two conceptual explanations generate contradictory hypotheses, they share the assumption that parenting may actually serve as a moderator of interparental conflict in the prediction of child problems. However, parenting practices have generally been tested as mediators in models of interparental conflict, without consideration of alternative or competing family process models (e.g., moderator models). In the rare instances when both mediation and moderation are tested in the same study (e.g., Davies, Harold, et al., 2002; Frosch & Mangelsdorf, 2001), the findings do not uniformly support the viability of mediational paths of parenting over moderating role or parenting.

Parent-Child Relationship Quality

Associations between individual differences in exposure to interparental conflict and parenting practices and parent-child relationship processes further suggest that parent-child relationship dimensions may be vital to elucidating indirect path models. Attachment theory is a particularly promising conceptual tool in taking indirect path models one step further in the specification of family process. Central to attachment theory is the proposition that children's quality of attachment to caregivers mediates the link

between parental emotional availability (e.g., sensitivity, responsiveness) and the development of normal or psychopathological functioning (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969; Cicchetti, Cummings, Greenberg, & Marvin, 1990). Given that protection is a primary function of the attachment relationship, variations in the quality of attachment patterns are assumed to reflect individual differences in the ability of the children to use the caregiver as a haven of protection and safety (Cicchetti et al., 1990; Colin, 1996; Kobak, 1999). However, the substantive scope of attachment theory has, at least until recently, been largely confined to identifying specific parenting (e.g., responsiveness) and child (e.g., temperament) attributes in isolation from the broader family system (see Thompson, 1997).

To address this gap (Cowan, 1997), the emotional security theory has postulated two channels through which attachment patterns may mediate interparental conflict. Paths relevant to addressing these pathways are illustrated in Figure 3.4. First, as shown in Paths 2, 5, and 7 in Figure 3.4, parenting disruptions that accompany chronic interparental discord may increase child psychopathology by undermining children's confidence in parents as sources of protection and support. In support of part of this hypothesis (i.e., Paths 2 and 5), studies have demonstrated that parental emotional availability (e.g., sensitivity, support) partly mediates the link between marital conflict and child-parent attachment security (Frosch, Mangelsdorf, & McHale, 2000; Owen & Cox, 1997). In expanding on these findings, structural equation modeling revealed that the mediational role of parenting difficulties in associations

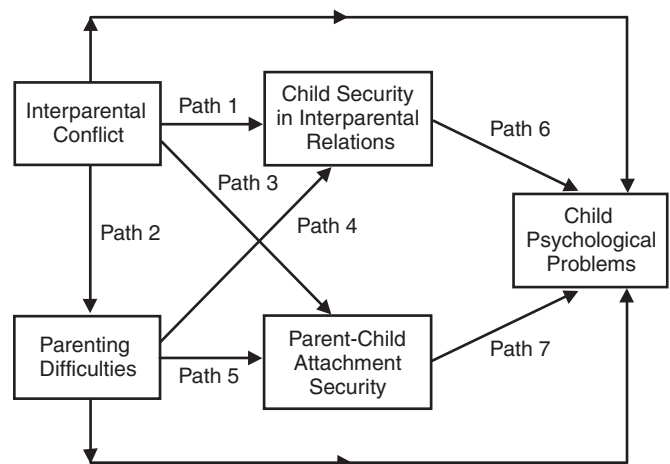

Figure 3.4 A conceptual model of the joint interplay between interparental conflict and parenting difficulties in predicting child security in family relationships and psychological adjustment.

between interparental conflict and early adolescent internalizing and externalizing symptoms was further mediated by children's doubts about the accessibility of their parents as support figures (Davies, Harold, et al., 2002).

Second, Paths 3 and 7 illustrate the hypothesis that exposure to interparental conflict may also be associated with child psychological problems by directly undermining child security in parent-child relationships. Witnessing frightening (e.g., violence, emotional volatility) and frightened (e.g., submissiveness, crying) parental behavior during interparental conflicts is specifically thought to compromise not only child security in the interparental relationship but also child confidence in parents as sources of protection and support (Owen & Cox, 1997). Consistent with this hypothesis, interparental conflict has been shown to predict insecure and disorganized parent-child attachment relations even after controlling for parental sensitivity and warmth (Frosch et al., 2000; Owen & Cox, 1997).

More research is needed to further elucidate associations between marital conflict and parent-child attachment. Given some null and inconsistent findings on the relationship between attachment and interparental conflict, it is possible that interparental discord predicts attachment difficulties only under certain contextual conditions (Belsky, 1999). For example, research by Das Eiden, Teti, and Corns (1995) indicates that the association between interparental discord and attachment difficulties specifically emerged when parents evidenced relational vulnerabilities (e.g., insecure adult attachment relations). Moreover, disentangling the constellation of relationships between specific interparental conflict behaviors and specific attachment patterns may also prove useful in future research. Specifically, forms of frightening and frightened spousal behaviors may have different implications for how children organize their attachment patterns. Frightened behavior manifested in submissiveness, crying, and fear may foster representations of the parent as incompetent and weak and, as a result, undermine child confidence in the parent as a source of protection and in the process lead to relatively coherent forms of insecure attachments (e.g., avoidance, resistance). Conversely, frightening parental behaviors characterized by aggression and coercion may not only undermine child confidence in parental support but also foster child representations of parents as sources of threat and alarm. As a result, these children may be at specific risk for developing disorganized attachments. In accordance with transactional conceptualizations of development, reciprocal feedback loops may exist between parent-child attachment patterns and interparental relations (Byng-Hall, 1999), with specific patterns of parent-child attachment

also regulating the quality of interparental interactions. For example, clinical observations suggest that dependency and distress underlying resistant attachment patterns serve a stabilizing function in some families by diverting attention away from serious interparental problems or fulfilling intimacy needs of parents in disengaged marriages (Byng-Hall, 1999; Marvin & Stewart, 1990).

The conceptual model in Figure 3.4 raises other key questions necessary to advance a comprehensive model of emotional security. Path 4 illustrates that poor parenting may, in itself, increase child insecurity in the context of interparental difficulties. Although comprehensive tests of this path await future research, findings from initial studies are intriguing (Davies & Forman, 2002). For example, Hennessy, Rabideau, Cicchetti, and Cummings (1994) reported that children with histories of physical abuse evidenced greater fear in response to simulated adult conflict than nonabused children (see Grych, 1998, for different results). Furthermore, Paths 6 and 7 raise questions about whether the magnitude of paths between emotional security and children's developmental paths vary as a function of the context of security (i.e., interparental versus parent-child) and the form of maladjustment (see Davies, Harold, et al., 2002).

Coparenting Relations

A common assumption of many theoretical frameworks is that discord between parents covaries with disruptions in the coparenting relationship or parental abilities to support each other and work together as a team in raising the children. For example, in the spillover hypothesis, the proliferation of distress from interparental discord is not necessarily limited to the parent-child subsystem abilities (e.g., Erel & Burman, 1995; Floyd et al., 1998). In fact, emotional difficulties with the spouse may be especially likely to be manifested in coparenting disruptions as attempts to undermine spousal authority in the family may be a powerful way to seek retribution for perceived emotional injustices stemming from the interparental relationship. Similarly, the principle of interdependency in family systems theory postulates that spousal discord reflects a larger constellation of transactional influences with coparenting disturbances, as perturbations in any one subsystem reverberate through other family relationships in a negative reciprocal cycle (e.g., Cox et al., 2001; P. Minuchin, 1985). Supporting these predictions, marital conflict has been associated with various disruptions in the ability of parents to jointly coordinate child-rearing activities, including disengagement, triangulation, hostility,

and disparagement (e.g., Floyd & Zmich, 1991; Katz & Gottman, 1996; McHale et al., 2004; Sturge-Apple et al., in press). Coparenting disturbances, in turn, have been associated with a wide array of child psychological problems (Belsky, Putnam, & Crnic, 1996; Leary & Katz, 2004; McHale, Johnson, & Sinclair, 1999) even after statistically controlling for other family processes such as marital conflict and parenting practices (e.g., Jouriles, Murphy, et al., 1991; McHale & Rasmussen, 1998; Schoppe, Mangelsdorf, & Frosch, 2001).

Although these findings are consistent with indirect paths between marital conflict, coparenting relationships, and child functioning, direct, systematic tests of the mediational role of coparenting have yet to be undertaken. In the rare instances in which the predictive roles of coparenting and interparental difficulties have been examined simultaneously in models of child functioning (Jouriles, Murphy, et al., 1991; McHale & Rasmussen, 1998), statistical models have primarily been utilized to evaluate the unique, additive effects of the family predictors. Thus, advances in models of interparental conflict in the broader family system will require more direct tests of the mediational interplay between interparental conflict and coparenting dimensions in the prediction of child coping and functioning. Moreover, even if the mediational role of coparenting processes is demonstrated, it is also important to progressively broaden the study of these indirect pathways in the larger family system. For example, some findings indicate that the mediational role of coparenting processes may be magnified or diluted by various family and child characteristics (e.g., McHale et al., 2002; Schoppe et al., 2001). In drawing attention to another knowledge gap, Path 2 in Figure 3.1 illustrates the largely untested assumption that child response and coping processes may ultimately account for the mediating role of coparenting relations in associations between interparental conflict and child adjustment.

CONTEXTUAL RISK AND PROTECTIVE MODELS OF INTERPARENTAL DISCORD

Although there is ample empirical support for both direct and indirect path models of interparental conflict, the research also indicates that there is substantial heterogeneity in the magnitude of child coping and response processes and parent-child relationship dynamics as mediators of interparental conflict. Thus, a key question remains: Why is there considerable diversity in these mediational pathways? From a developmental psychopathology perspective, individual development is regarded as operating within open

systems characterized by an ongoing transactional interplay between an active changing organism in a dynamic changing context (Cicchetti, 1993; Davies & Cicchetti, 2004; Granic & Hollenstein, 2003). In applying this notion to work on interparental conflict, a derivative hypothesis is that individual differences in the strength of direct and indirect pathways will lawfully vary as a function of the broader multilevel matrix of contextual characteristics.

Open system conceptualizations in developmental psychopathology do pose a number of formidable challenges to understanding the role of contextual processes in mediational pathways across multiple domains and levels of analysis. First, there are important differences in the nature and properties of contextual risk factors. For example, in attempting to provide a parsimonious account of risk and protection across multiple topical areas in developmental psychopathology, Garmezy (1985) offered a tripartite framework consisting of (1) child dispositional attributes, including temperament, personality, and gender; (2) family characteristics, including family climate, parenting practices, and parent psychopathology; and (3) extrafamilial characteristics, including friendships, community, and cultural characteristics.

Second, in open systems conceptualizations, contextual characteristics can have different effects as architects of pathways between interparental and child functioning. Figure 3.5 provides a visual depiction of four of the more prominent roles of contextual factors in multivariate frameworks of interparental conflict. Models 1 and 2 in Figure 3.5 illustrate that mediational pathways may best capture the interplay between interparental conflict and a given contextual characteristic in the prediction of child maladaptation. Because it is often plausible to interchange interparental conflict and many contextual characteristics in conceptual roles as mediators of one another, precisely mapping the etiological pathways remains a critical challenge. Consistent with indirect path models, the first model proposes that child, family, and extrafamilial attributes may reduce the strength of direct and indirect pathways by partially mediating or accounting for the effects of interparental conflict. Thus, alternative contextual characteristics may also serve as mechanisms that help to explain why children exposed to destructive interparental conflict are at greater risk for developing psychopathology. In contrast, the second model postulates that contextual characteristics may influence child coping and adjustment indirectly through their associations with interparental conflict. Thus, mediational pathways may be reversed, so that interparental problems are more proximal mediators of contextual characteristics. However, identifying contextual characteristics as distal risk

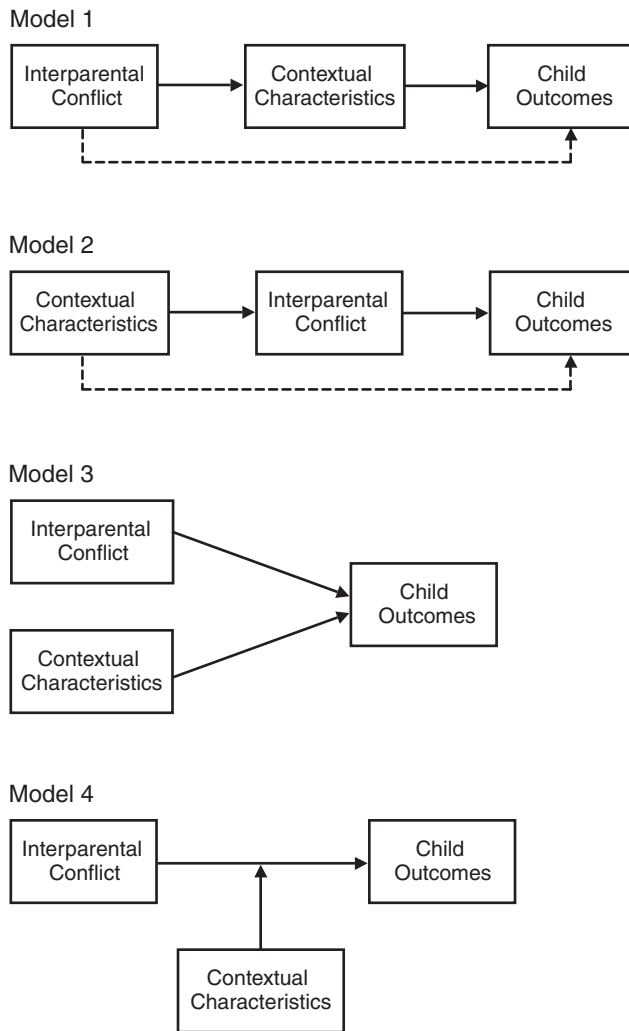

Figure 3.5 Conceptual models depicting the possible interplay between interparental conflict and contextual characteristics in the prediction of child maladaptation.

factors in a study of interparental conflict does not necessarily relegate it to a secondary conceptual status. Rather than falling into the reductionist trap of regarding “the smallest and most proximal event as the ultimate cause” (Emery et al., 1992, p. 910) of child psychopathology, distal effects of contextual characteristics are still regarded as playing an integral role in understanding the genesis of child psychopathology.

The final two models illustrate the possibility that mediational or causal chains may fail to adequately reflect the nature of the relationship between interparental conflict and a particular contextual characteristic in predicting child maladaptation. Even though the two factors may fail to explain one another’s effects, the third model in Figure 3.5 indicates that interparental conflict and any given contextual risk can still operate as independent predictors

In accordance with this approach, some developmental psychopathology studies have aggregated multiple indices of risk into a single composite based on the tacit assumption that each risk factor contributes uniquely to predict child problems in an *additive effects* fashion (Luthar, 1993; Sameroff & Seifer, 1990). In contrast, the fourth model in Figure 3.5 highlights an alternative possibility that the interplay between interparental conflict and a given contextual characteristic may not necessarily be additive in nature. Potentiating and protective frameworks in developmental psychopathology specifically postulate that interparental conflict and contextual risk may interact in multiplicative or synergistic ways. By addressing questions of who is most and least at risk and when is the risk most or least pronounced, these frameworks have proven to be useful tools in identifying sources of variability in associations between interparental conflict and child functioning. Potentiating factors in these models are specifically conceptualized as amplifying or exponentially increasing the risk posed by interparental conflict. Conversely, protective factors serve to diminish or offset the deleterious effects of interparental conflict.

Third, contextual factors in open systems may vary in the locus of their effect in etiological pathways involving interparental conflict and child adjustment. Incorporating contextual characteristics into direct path models may advance an understanding of any link in the mediational chain, including links between interparental conflict and children’s coping and response processes or children’s coping and response processes and their developmental trajectories of adjustment. In a similar fashion, contextual factors may alter associations between interparental conflict and parent-child relationship dynamics, parent-child relationship dynamics and child adjustment trajectories, or both.

Given that contextual characteristics can vary in terms of form, function, and the locus of effect, we organize our following discussion around the theoretical value of distinguishing contextual attributes along these three dimensions. Consistent with the tripartite framework developed by Garmezy (1985), we selectively discuss how the three classes of contextual factors (i.e., child attributes, family characteristics, extrafamilial characteristics) may help to advance knowledge on direct and indirect path models of interparental conflict.

Child Dispositional Attributes

Although it is important to note that a variety of child attributes may figure prominently in the variability of children’s adaptation to interparental conflict, we selectively

focus on three primary dimensions for the sake of illustration: gender, age, and temperament.

Child Gender

In support of a “male vulnerability” model, many initial tests of the moderating effects of gender demonstrated that associations between marital conflict and child maladjustment were stronger for boys than girls (E. M. Cummings & Cummings, 1988). However, a rigorous analysis of more contemporary studies reveals that it is difficult to draw any clear-cut, simple conclusions regarding the role of gender. Many recent studies have produced complex and inconsistent results, with large sample studies and meta-analyses failing to find support for moderating effects (e.g., Buehler et al., 1997; Jouriles, Bourg, & Farris, 1991). Resolving this complexity may require greater sensitivity to the possibility that gender may operate in different ways across levels or domains of children’s functioning. For example, the male vulnerability model may be applicable only in the prediction of specific forms of psychopathology (e.g., conduct problems). In expanding on this theme, it is also possible that girls and boys evidence comparable levels of distress that are manifested in different ways (Davies & Lindsay, 2001). Girls, in particular, may be especially likely to exhibit greater distress with corresponding increases in conflict hostility (E. M. Cummings et al., 1989; Davies, Myers, et al., 1999; Grych, 1998), especially when distress is reflected in subtle, covert channels (E. M. Cummings et al., 2000). Thus, researchers would do well to delineate gender-specific pathways in models that integrate the study of children’s specific reactivity to conflict with indices of their global psychological adjustment (Davies & Lindsay, 2001).

Another key task facing researchers is to uncover the wide range of developmental and socialization pathways that lead to variability in outcomes experienced by boys and girls in high-conflict homes. For example, the relative susceptibility of boys and girls to marital conflict may vary across the developmental stages of the children (Hops, 1995). Boys’ susceptibility to maladjustment, particularly in the form of externalizing symptoms, may be stronger in childhood than girls’. According to one biological explanation, boys may have weaker neuropsychological and psychobiological systems in early childhood that may serve to potentiate the stressful effects of interparental conflict (Emery, 1982). However, this explanation does not readily account for findings indicating that girls may evidence greater vulnerability to interparental discord than boys as children progress into adolescence (E. M. Cummings & Davies, 1994a; Davies & Windle, 1997; Hops, 1995; Pe-

tersen, 1988). According to the gender intensification hypothesis (Hill & Lynch, 1983), increasing physical differentiation between boys and girls during puberty sets in motion more pressure for girls to conform to conventional social roles of valuing close interpersonal and family relationships. In turn, this greater concern and preoccupation with maintaining harmonious family relations may increase girls’ sensitivity to interparental conflict and cause them to react more negatively than boys (Davies & Lindsay, 2001, 2004; Davies & Windle, 1997). Alternatively, developmental models stress that the timing and nature of some developmental challenges may vary by gender. For example, girls not only perceive puberty as a more stressful event than boys do, but they are also more likely to experience the challenge of coping with other stressful events, such as the transition to the larger, more impersonal confines of secondary school systems (Windle, 1992). Thus, this dense temporal clustering of stressors may place undue burdens on coping abilities and resources and exacerbate the deleterious effects of interparental conflict for girls.

Age and Developmental Level

Although age is increasingly acknowledged as a potential moderator in models of interparental conflict (E. M. Cummings & Davies, 1994a; Grych & Fincham, 1990), it is difficult to decipher whether children in any specific age group or developmental period are, in any broad sense, more vulnerable to interparental conflict (Buehler et al., 1997).

Part of the challenge is that age in our process model is conceptualized as a general marker for a multiplicity of changes in biological and experiential processes. Accordingly, different domains of functioning change in different ways with age, with some changes resulting in greater risk for children and others resulting in less risk. For example, the vulnerability of preschool children to interparental conflict may be particularly pronounced by virtue of their dispositions to experience fear, self-blame, and threat in response to conflict (e.g., Covell & Abramovitch, 1987; E. M. Cummings et al., 1989; Davies, Myers, et al., 1999; Jouriles, Spiller, Stephens, McDonald, & Swank, 2000), low levels of perceived competence in coping (Cummings et al., 1991; Grych, 1998), and limited ability to enlist coping strategies to regulate affect (El-Sheikh & Cummings, 1995). Yet, relative to older children and adolescents, preschoolers’ lower sensitivity to adult problems, briefer histories of exposure to interparental conflict, and weaker disposition to mediate conflicts may serve as protective factors that offset this risk.

Distinguishing among different forms of child maladjustment may also be critical in specifying the moderating

role of age. Age-related vulnerability to marital conflict may be limited to specific forms of psychopathology rather than generalizable to multiple patterns of symptomatology. For example, whereas young children may largely express their distress in the form of externalizing difficulties in stressful interpersonal contexts (E. M. Cummings & Davies, 1994a), tendencies to exhibit internalizing symptoms and negative self-appraisals in response to stress increase with age (Jouriles et al., 2000). Thus, in the stressful context of repeated interparental conflict, younger children may be especially likely to express their distress in the form of externalizing symptoms, whereas older children may be increasingly prone to developing internalizing difficulties.

In the context of our process model, the moderating role of age may vary across different parts of the mediational pathways involving interparental conflict, children's response processes, and their developmental outcomes. For example, Davies, Myers, and colleagues (1999) found that late adolescents were significantly more likely to distinguish between destructive and constructive histories of interadult conflict in their appraisals of long-term relationship problems than were younger children. Likewise, Jouriles and colleagues (2000) reported that appraisal of self-blame was a more powerful predictor of child internalizing symptoms for 10- to 12-year-old children than for 8- to 9-year-old children. Thus, the key aim may involve not simply searching for age-specific vulnerabilities to interparental conflict, but rather explicating the specific locus of the moderating effects of age at different parts of the multichain process models of interparental conflict.

Temperament

Several conceptual frameworks have explicitly hypothesized that dimensions of temperament function as potentiating and protective factors in associations between interparental conflict and children's coping and adjustment (Davies & Cummings, 1994; Grych & Fincham, 1990). Initial empirical tests of this hypothesis have revealed that dimensions of difficult temperament appear to potentiate the risk interparental discord posed to adolescents' trajectories of psychological adjustment (Davies & Windle, 2001). However, beyond this single study, little is known about the nature of the multiplicative interplay between temperament and interparental conflict. Thus, examining the potential protective and potentiating effects of temperament and other behavioral and personality dispositions is an important research direction, especially in light of intriguing relations between children's behavioral difficulties and their adaptation to adult and marital dis-

cord (e.g., E. M. Cummings, Iannotti, & Zahn-Waxler, 1985; Davies & Windle, 2001).

As knowledge of these moderating effects accumulates, understanding why children with certain dispositions are more vulnerable to marital discord will also be a critical research direction. Conceptual frameworks that articulate the mechanisms that underlie the moderating effects of temperament may serve as valuable guides in this area of inquiry (Davies & Cummings, 1994; Grych & Fincham, 1990). For example, does heightened reactivity to negative events experienced by children with difficult temperaments increase their risk by magnifying their sensitization to conflict (Grych & Fincham, 1990)? Alternatively, do key features of difficult temperament (e.g., negative mood, high activity, poor attention) prompt children to rely on narrow, rigid, and maladaptive ways of coping with interparental conflict (Grych & Fincham, 1990)? Or, is it possible that transactional processes are operating whereby difficult temperaments tax the already fragile family relationships and, in turn, further fuel children's behavioral difficulties through exposure to greater family conflict (Davies & Cummings, 1994; Davies & Windle, 2001)?

Family Characteristics

A principle common to both family systems theory and the organizational perspective in developmental psychopathology is that functioning in any one domain is defined by and part of a broader constellation of functioning in the system as a whole. In the family system, organization, patterning, and regularity in the family as a whole regulates and is regulated by the interplay among interparental, parent-child, and coparenting subsystems (Cox & Paley, 1997; Mikulincer, Florian, Cowan, & Cowan, 2002; P. Minuchin, 1985; S. Minuchin, 1974). Consequently, interparental conflict styles can be usefully conceptualized as integral components of broader patterns of boundary maintenance (e.g., implicit rules for exchanging material and psychological resources across family subsystems), affective functioning, and relationship quality in the family, which, in turn, may further define how children adapt to interparental and family processes.

Advances in the study of family-level and triadic systems (e.g., conflict, instability, cohesion, expressiveness, support) are proving useful in integrating the examination of interparental conflict in a familywide model of functioning. For example, although McHale and Rasmussen (1998) did not explicitly examine whether observations of family-level perturbations mediated associations between interparental and inraparental distress and child functioning,

family perturbations did uniquely predict child aggression 3 years later even after statistically controlling for intra-parental and interparental functioning. As another example, Davies, Cummings, et al. (2004) used cluster-analytic methods to identify individual differences in the higher-order organization of family functioning based on the quality of relationships in the interparental, coparental, and parent-child subsystems. Consistent with previous work on family systems theory (Belsky, Rovine, & Fish, 1989; Cox & Paley, 1997; Kerig, 1995; Kretchmar & Jacobvitz, 2002; Marvin & Stewart, 1990), families fit into one of four profiles: (1) cohesive families, who maintained well-defined, flexible boundaries between subsystems that permitted access to relationship resources and support while also respecting autonomy; (2) enmeshed families, who experienced weak boundaries across family subsystems and, as a result, displayed high levels of conflict, hostility, and psychological control; (3) disengaged families, who experienced overly rigid, inflexible, and distant boundaries that are manifested in high levels of discord, hostility, and detachment across family subsystems; and (4) adequate families, who, despite some discord, generally exhibited healthy family functioning. Furthermore, in comparison to children in cohesive families, the results indicated that disengaged and enmeshed families exhibited greater signs of insecurity in the interparental relationship concurrently and internalizing and externalizing symptoms both concurrently and 1 year later (also see Belsky & Fearon, 2004; O'Connor, Hetherington, & Reiss, 1998). Although these studies lend support to the notion that interparental conflict may exert an impact on child mental health through its inextricable relationship with broader configurations of family functioning, direct tests of family configurations as intervening or mediating mechanisms in associations between interparental conflict and child maladjustment await further research.

Sibling Relations

Little is known about the joint influence of parental conflict and sibling relationship quality on children's adjustment, but the available evidence supports sibling relationships as also factoring in the effects of interparental conflict (Dunn & Davies, 2001). Contemporaneous and prospective relations between marital conflict and sibling conflict and poor relationship quality are reported (Brody, Stoneman, & McCoy, 1992; Stocker & Youngblade, 1999). Furthermore, research has begun to address the family (e.g., differential parental treatment, parental hostility) and child (e.g., self-blame) processes that may account for relationships among interparental conflict, compromised sibling relations, and child adjustment prob-

lems (McGuire, Dunn, & Plomin, 1995; Stocker & Youngblade, 1999).

Although the study of siblings constitutes an emerging area of study in the interparental conflict literature, the relatively scant literature from a process-oriented and appropriately familywide perspective on this topic offers little support for any reasonably comprehensive model for understanding siblings as an influence in the context of interparental discord. Addressing this gap, Dunn and Davies (2001) recently presented an initial conceptualization for indirect and direct pathways between interparental discord and quality of sibling relations. Building on the broader literature concerning direct and indirect pathways (E. M. Cummings & Davies, 2002), indirect pathways were hypothesized to reflect links between marital discord, the quality of both mothers' and fathers' relationships with children (e.g., negativity in parent-child relationships; more differential parent-child negativity), and quality of sibling relationships. Direct paths were also hypothesized, reflecting direct pathways between interparental hostility and children's negative relationships with their siblings (Dunn et al., 1998).

Consistent with potentiating and protective frameworks, other conceptualizations have cast sibling relationships as potential protective factors in high-conflict homes. Jenkins and colleagues (1989) reported that seeking contact with a sibling was a commonly used strategy for children coping with interparental conflict. E. M. Cummings and Smith (1993) demonstrated that positive affect increased among female siblings during exposure to adult conflict involving the mother. In directly testing sibling relations as a moderator, Jenkins and Smith (1990) reported that the association between interparental conflict and child symptoms was significantly weaker in magnitude for children with good sibling relations than for children with poor sibling relations. In fact, even the mere presence of a sibling may buffer children from the effects of family stress (Kempton, Armistead, Wierson, & Forehand, 1991; Sandler, 1980). By the same token, researchers must be careful not to simply assume that siblings will uniformly serve as buffers of interparental conflict. As a case in point, Nixon and Cummings (1999) found that children with disabled siblings reported greater distress, personal responsibility, and impulses to intervene in family conflicts than children without disabled siblings. Collectively, this body of research generates several important questions in advancing risk and potentiating models: Does being a recipient of protection and nurturance from a sibling largely explain why good sibling relations buffer children from interparental conflict? Do children incur benefits or, alternatively, psy-

chological burdens from being the provider of safety and nurturance for a sibling?

Parent Psychological Symptoms

Parent psychological symptoms have also been implicated as central processes in indirect pathways of interparental discord. However, the nature of the interplay between parent psychological symptoms and interparental conflict has yet to be clearly elucidated. Supporting additive models, some studies have indicated that parental depressive symptoms and interparental discord are each independent predictors of child psychological maladjustment (Fendrich, Warner, & Weissman, 1990; Shaw & Emery, 1987). Conversely, some research and theory indicate that parent psychological symptoms may serve as distal risk factors that increase child vulnerability largely through their associations with family disturbances such as interparental conflict (E. M. Cummings & Davies, 1994b; Cummings, Keller, & Davies, in press). Still other work suggests that parent psychological symptoms are more proximal risk factors that mediate interparental conflict, at least under some conditions (Davies, Dumenci, & Windle, 1999; Downey & Coyne, 1990; Papp, Cummings, & Schermerhorn, 2004).

Variations in the conceptual ordering of marital conflict and parental psychological attributes across these studies may result from the specific expression of parental symptoms, marital conflict, and child psychopathology. For example, Downey and Coyne (1990) postulated that the specific mediational interplay between interparental conflict and parent depressive symptoms depends on the form of child maladjustment. Whereas parent depressive symptoms were specifically hypothesized to account for links between marital discord and child internalizing symptoms, marital discord was proposed to mediate the links between parent depressive symptoms and child externalizing symptoms. Supporting these hypotheses, maternal depressive symptomatology has been shown to mediate prospective associations between marital discord and adolescent depressive symptoms, and marital discord accounted for prospective associations between maternal depressive symptoms and adolescent delinquency (Davies, Dumenci, & Windle, 1999; also see Fendrich et al., 1990; Shaw & Emery, 1987).

Differences in how interparental conflict is expressed may also account for inconsistencies in mediational interplay involving parental adjustment problems and interparental conflict. In drawing on evidence that interparental dysphoria is a distinct dimension of conflict (Davis, Sheeber, Hops, & Tildesley, 2000), Du Rocher Schudlich and Cummings (2003) specifically examined

constructive, destructive, and dysphoric marital conflict as mediators in links between parental depressive symptoms and child psychological symptoms. Whereas constructive and destructive conflict between parents failed to explain the risk posed by parental depressive symptoms, dysphoric marital conflict was a robust mediator in associations between parental depressive symptoms and child internalizing symptoms.

The nature of mediational pathways between marital conflict, parental attributes, and child problems may also depend on specific types of parental characteristics. On the one hand, some forms of parental psychopathology may assume a more distal role. For example, conceptual models have consistently cast interparental conflict as a central explanatory mechanism for why children exposed to parental drinking problems experience greater psychological problems (El-Sheikh & Cummings, 1997; Windle & Davies, 1999). In support of these models, empirical evidence has indicated that interparental conflict is a robust intervening mechanism linking parental problem drinking to child maladjustment (e.g., El-Sheikh & Flanagan, 2001; Keller, Cummings, & Davies, in press). On the other hand, other forms of psychopathology may assume more proximal roles as mediators of marital conflict (Emery, Waldron, Kitzmann, & Aaron, 1999). For example, in a study that examined broader constellations of parental psychological symptoms (e.g., anxiety, hostility, depressive symptoms), both maternal and paternal symptoms mediated associations between interparental discord and child maladjustment (Papp, Goeke-Morey, & Cummings, 2004). Although it is still premature to draw firm conclusions, one possibility is that the proximal risk posed by parental psychological distress in models of interparental discord may become amplified as children are exposed to progressively broader constellations of parental emotional difficulties.

It is also possible that children's stakes in interparental conflict differ depending on the specific adjustment patterns of the parents. For example, a recent study by Papp, Cummings, and Schermerhorn (2004) indicated that the multiplicative interaction between interparental discord and maternal psychological functioning (e.g., anxiety, depression) predicted child internalizing and externalizing symptoms above and beyond the sum of the risk factors considered singly. If specific forms of parental adjustment do prove to be consistent moderators of interparental conflict, an important next step is to more precisely identify the locus of the interaction in mediational pathways. For example, the emotional security theory specifically postulates that signs of adult psychological vulnerability, like parental symptoms, may potentiate or prime the impact

that exposure to interparental conflict has on children's concerns about their security in the interparental relationship. Thus, parental depressive symptoms may amplify associations between interparental conflict and child psychopathology by more specifically catalyzing the threat that interparental conflict poses for child security. Another hypothesis derived from the emotional security theory is that insecure children may be especially vulnerable to developing psychopathology when they also have to cope with other sources of adversity in the family (e.g., parental psychological maladjustment; see Davies, Harold, et al., 2002).

Indirect pathways between interparental conflict, parenting practices, and child maladjustment may also vary as a function of parent depressive symptoms. Family systems theory specifically postulates that family perturbations, including parental maladjustment, may provoke subsequent reorganizations in family functioning and function as architects of interdependencies among interparental and parent-child subsystems (Grych, 2002). However, precisely how adult characteristics alter these pathways is not well understood. Guided by risk and potentiator models, it is plausible that difficulties regulating and containing negative spillover effects from interparental to parent-child subsystems are amplified for parents who are already experiencing psychosocial vulnerabilities. In support of this hypothesis, research has suggested that associations between interparental conflict and parenting difficulties or paternal hostility may be especially pronounced at high levels of maternal depressive symptoms (Davies, Sturge-Apple, et al., 2004) or paternal violent tendencies (Margolin, Gordis, & Oliver, 2004). Other models of developmental psychopathology caution against assuming that inherently negative characteristics necessarily have potentiating effects that are fixed across multiple contexts (E. M. Cummings et al., 2000; Toth & Cicchetti, 1996). Thus, under some contexts, the transmission of distress across interparental and parent-child subsystems may actually be diluted when parents evidence specific vulnerabilities (Davies, Sturge-Apple, et al., 2004).

Extrafamilial Characteristics

Larger ecological contexts in the form of culture, extended kin networks, neighborhood quality, school climate, exposure to media, and friendship and peer relations may alter the nature and magnitude of pathways between marital conflict and child adjustment. As Parke (1998, p. 4) noted, "The field of family psychology is increasingly recognized as contextualized and embedded in a set of complex extended family, neighborhood, institutional, and cultural

systems," and "one of the major challenges over the next decade is to better understand the interplay between family and other social systems." Although the ecological context consists of multiple possible levels of analysis (Bronfenbrenner, 1979), the scope of our review must, of necessity, be limited to illustrative contexts: peer, community, and cultural settings.

Peer Relations

Supporting a social ecological model, there is now a relatively substantial literature linking interparental difficulties to problematic peer relationships (e.g., Erel et al., 1998; Gottman & Katz, 1989; McHale et al., 1999; Stocker, Ahmed, & Stall, 1997; Stocker & Youngblade, 1999). Given these demonstrated links, the next step for a developmental psychopathological and process-oriented perspective is to identify the family (e.g., parent-child hostility) and intrachild (e.g., perceptions of marital conflict; emotional regulation) processes that mediate associations between marital conflict and children's peer relations (e.g., Parke et al., 2001; Stocker & Youngblade, 1999). In drawing on conceptualizations of internal working models (e.g., Bowlby, 1982), the emotional security theory considers child representations of family relationships to be key components of security that mediate relationships between marital conflict and child socioemotional functioning in multiple social contexts, including peer relationships (Davies, Harold, et al., 2002). Consistent with this hypothesis, Du Rocher Schudlich, Shamir, and Cummings (2004) reported that children's internal representations of negative mother-child and father-child relationships mediated links between destructive interparental conflict and their negative dispositions for hostile conflict behavior with peers.

Researchers are also facing the challenge of understanding the interplay between peer relations (i.e., exosystem) and marital conflict (i.e., microsystem) in the larger context of children's developmental outcomes over time. For example, interparental conflict may be a causal agent responsible for the early onset of some forms of maladjustment, whereas peer relations may play an increasingly important role in the developmental course of problems thereafter (Fincham, Grych, & Osborne, 1994). Moreover, complementary conceptualizations have stressed that peer and friendship quality may buffer children from the deleterious effects of interparental conflict (Wasserstein & LaGreca, 1996). In furthering a process-oriented approach, progress in this area will require specification of models that are sensitive to the multidimensional nature of peer relations and the various functions (e.g., mediator, moderator) they may assume in understanding direct and

indirect path models of interparental conflict (Parke et al., 2001).

Community

As components of the exosystem in ecological-transactional frameworks of development (Bronfenbrenner, 1979; see also Cicchetti & Lynch, 1993; Lynch & Cicchetti, 2002), community factors (e.g., schools, neighborhood) constitute another important dimension for understanding the impact of interparental conflict on children. For example, Jenkins and Smith (1990) reported that community relations and activities such as positive recognition for school or extracurricular activities and the presence of close relations with extrafamilial adults (e.g., teachers) served as protective factors in associations between marital discord and child psychological symptoms. Although there has been very limited work on identifying the role that community factors play in models of interparental conflict, some promising research directions are evident. For example, one area of recent activity has been the examination of community violence as an ecological context for interparental conflict and violence. Community violence and aggression in the home have been linked to similar disturbances in coping and adjustment among children (Kitzmann et al., 2003; Lynch & Cicchetti, 2002; Margolin & Gordis, 2000). Given that community and family violence are theorized to be complexly interrelated in affecting children (Lynch & Cicchetti, 2002; Margolin & Gordis, 2000), future research is needed to understand the nature of the joint effects (e.g., additive, multiplicative, mediational) of community and marital disturbances on child development (e.g., Forehand & Jones, 2003).

Culture

Little is known about interrelations between marital conflict and children's coping and adjustment beyond White, middle-class U.S. or European samples (Depner, Leino, & Chun, 1992; Gonzalez et al., 2000; Parke & Buriel, 1998). Because the effects of interparental conflict on children have rarely been considered across diverse cultural or ethnic groups, questions remain regarding the cross-cultural applicability of relations between marital and child functioning. At one level, ethnicity has often been treated as a rough proxy for culture. Support for ethnic specificity in spillover of family stress is evidenced by stronger associations between family stress and family conflict in Caucasian families than in Hispanic families (Barrera, Li, & Chassin, 1995). On the other hand, tests of direct and indirect path models of interparental conflict are remarkably similar across studies that have independently utilized samples of predominantly Cau-

casian, middle-class samples and samples of multiethnic, low-income families (Fauber et al., 1990; Gonzalez et al., 2000; Grych, Fincham, et al., 2000; K. M. Lindahl & Malik, 1999; Tschann et al., 2002), thereby failing to support the hypothesis that ethnicity may protect children from the effects of marital conflict.

At another level, cross-cultural research may provide an especially revealing test of culture as a potentially powerful moderator of relations between marital conflict and children, given the likely amplified differences in ecological contexts (e.g., differences at the level of the macrosystem). For example, although parental and neighborhood processes are regarded as key factors contributing to relatively high rates of violence among Latin American children, adolescents, and young adults (Yunes & Zubarew, 2001), little research has been directed toward understanding marital and family processes in Spanish-speaking, Latin American families. In a rare study comparing responses of U.S. and Latin American children to marital conflict, E. M. Cummings, Wilson, and Shamir (2003) found considerable cross-cultural similarities in child adaptation to conflict, as evidenced by links between interparental conflict and child maladjustment and child reactivity to variations in marital conflict resolution. At the same time, culture moderated the amplitude of some relationships, with the pattern of findings suggesting that Chilean children were more sensitive to marital discord than U.S. children. Although these differences were small, one interpretation is that children's emotional security may be more closely tied to interparental discord in the collectivistic Chilean culture. Recent comparisons of responses of U.S. and Israeli kindergartners to analogue presentations of resolved and unresolved marital conflicts have also revealed many cross-cultural similarities in child reactions to marital conflict, especially in their sensitivity to escalating conflicts (Shamir, Cummings, Davies, & Goeke-Morey, in press). At the same time, the findings for resolved and unresolved conflicts supported the notion that U.S. children weight conflict resolution more heavily than Israeli children. Although further research is needed before drawing any conclusions, an intriguing interpretation is that variation in the geopolitical context accompanying the Israeli-Palestinian conflict may have contributed to these cultural differences.

DEVELOPMENT OVER TIME IN CONTEXTS OF INTERPARENTAL CONFLICT

Although models of direct and indirect pathways in the context of risk and protective factors underscore the dynamic

nature of developmental processes, the value of developmental psychopathology cannot be fully realized without embedding the study of maladaptation within broader developmental windows than a single snapshot or narrow temporal clip. As illustrated in Path 5 of Figure 3.1, developmental models involve understanding the changing challenges and capacities of children in the context of shifting constellations of risk and protective factors over successive developmental periods.

The Timing and Duration of Adversity

Even though the majority of studies have tacitly treated interparental conflict as a static, stable trait, a developmental perspective considers risk factors, such as interparental conflict, as potentially dynamic processes (Fincham et al., 1994). In drawing attention to the temporal dimension of risk and protection, Cicchetti and colleagues distinguish between transient and enduring risk and protective factors in their developmental models (Cicchetti, 1989; Cicchetti & Toth, 1995). Whereas transient factors reflect relatively short-term, temporary states, enduring factors have relatively protracted life spans that can potentially last over periods of years. Because different couples face unique arrays of dispositions, challenges, and stressors, it is likely that there is considerable interfamilial variability in the enduring or transient nature of interparental conflict. Thus, drawing from literature on parental psychopathology (e.g., Seifer, 1995), one hypothesis is that the degree of risk posed by interparental conflict is a direct function of the chronicity of the parents' problems. At the same time, the enduring bouts of interparental discord may not be universally more powerful than transient bouts of conflict in predicting child problems, especially if transient conflicts are reflecting severe forms of destructive conflict (e.g., violence).

Variations in the developmental timing of the risk factor may also be associated with lawful differences in child adaptation and maladaptation. Thus, age differences in susceptibility to the effects of interparental conflict may reflect the operation of sensitive periods, a process in which specific environmental influences become particularly acute within certain windows of development. However, despite its conceptual appeal in developmental psychopathology, the concept of sensitive periods has rarely been implemented in the study of children's adaptation to interparental conflict. Thus, it can be hypothesized that the stress of living with chronic interparental conflict may more easily overwhelm adolescents, who, by virtue of their unique developmental status, experience (1) greater interpersonal sensitivity to family adversity, (2) a number

of challenging developmental tasks (e.g., autonomy from parents, establishment of romantic relationships, identity development), and (3) peak occurrence of stressful life events (Buchanan, Maccoby, & Dornbusch, 1991; Davies & Windle, 2001; Gelfand & Teti, 1990). Alternatively, it is plausible that the emerging dimensions of interpersonal understanding (e.g., concerns about safety and vulnerabilities of parents) in conjunction with relatively limited coping repertoires and support networks of young children may magnify the deleterious impact of interparental conflict (Cicchetti et al., 1990).

Developmental Periods

Building on the concept of sensitive periods, development can be further conceptualized as a series of developmental challenges that emerge as prominent at a given period and remain important throughout an individual's lifetime (Cicchetti, 1993). Because these developmental challenges constitute a period of normative transition for most, if not all, individuals and require significant reorganization in functioning, some level of change and discontinuity is expected by definition (Graber & Brooks-Gunn, 1996). At each developmental stage, individuals are faced with resolving a number of significant tasks across multiple domains of functioning. For illustrative purposes, Table 3.1 provides an overview of some developmental challenges from birth through adolescence (Cicchetti, 1991; Sroufe & Rutter, 1984). Given that these tasks are already challenging in themselves, their successful resolution may be particularly sensitive to the effects of risk and protective factors.

Integrating developmental challenges within risk models, Graber and Brooks-Gunn (1996) posited that transition-linked turning points, which are characterized by significant life events in the context of challenging periods of reorganization and transition, have a particularly enduring impact on subsequent development. Further applying these concepts to models of interparental conflict, the emotional security theory specifically postulates that prolonged concerns about emotional security in family relationships (e.g., interparental, parent-child) requires considerable expenditure of biopsychosocial resources necessary to regulate attention, affect, thought processes, and action tendencies. Diminished reserves of energy, in turn, are theorized to disrupt children's abilities to marshal physical and psychological resources necessary to successfully resolve stage-salient tasks. Thus, in this process, concerns about security are thought to broadly facilitate psychological maladaptation by disrupting children's abilities to meet developmental challenges (Davies & For-

TABLE 3.1 Developmental Challenges Faced by Children from Infancy through Adolescence

Developmental Period	Stage-Salient Challenges
Infancy	Modulation of arousal Physiological regulation Harmonious, synchronous interactions with caregivers Secure attachments with primary caregivers Interpersonal trust
Toddler	Awareness of self as distinct Exploration of social and object worlds Emotion regulation and management Awareness and responsivity to standards Mastery, persistence, and problem solving Autonomy Sociability Understanding of internal emotion states of others
Preschool	Flexible self-control Self-reliance Initiative Awareness of social roles Gender role development Establishing effective peer relations Empathy and prosocial behavior
Childhood	Social understanding (equity, fairness) Gender constancy Same-sex friendships Peer relations and reputation Sense of industry (competence) Social agency School adjustment Internalization of standards of conduct
Adolescence	Flexible perspective taking Abstract thinking Moral reasoning Reconciling ideal world with real world Loyal same-sex friendships Establishing romantic relationships Balancing emotional autonomy with relatedness to parents Identity development Interpersonal intimacy Sexuality Risk management (e.g., substance use, sexual promiscuity)

man, 2002; Davies, Harold, et al., 2002; Thompson & Calkins, 1996). In accordance with the orthogenetic principle (Cicchetti, 1993), the emotional security theory further postulates that interparental conflict may ultimately increase long-term patterns of maladaptation by disrupting children's abilities to resolve contemporaneous developmental challenges. Through the process of hierarchical motility, old psychological characteristics and structures, though not evidencing a one-to-one correspondence with new forms of functioning, are specifically carried over and incorporated into evolving new structures over time

(Cicchetti & Cohen, 1995). Consistent with this notion, early emerging difficulties with emotion regulation and working models of family relationships among toddlers from high-conflict homes may disrupt children's abilities to successfully resolve the task of developing peer relationships in childhood and romantic relationships in adolescence (Amato & Booth, 2001).

Developmental Trajectories

Conceptualizing development as guided by the transactions between a multifaceted, changing child and the multilayered, dynamic context, developmental psychopathology frameworks commonly assume that there are multiple, diverse developmental trajectories of child adjustment. Metaphors enlisted to represent the multiplicity of pathways in development commonly include a branching tree (Sroufe, 1997) and branching railroad tracks (Bowlby, 1973). Following the branching tree metaphor, normal development can be understood in terms of growth close to the trunk of the tree, whereas abnormal development is reflected in branches growing farther from the tree. Thus, disorder is defined by successive and changing patterns of deviation from normality resulting from the interplay between intra- and extraorganismic processes rather than something that solely resides as a static intrapersonal trait (Sroufe, 1990). Moreover, although it is more difficult to reclaim normal trajectories of development as individuals progressively continue along maladaptive pathways, change is always possible, and individuals may fluctuate between normal and abnormal development over time.

Accordingly, solely focusing on continuity of development limits the ability to identify dynamic changes in child functioning, whereas exclusively tracking discontinuity may underestimate continuities reflecting processes by which current functioning builds on past functioning. Moreover, there are multiple levels of continuity and discontinuity (see Caspi & Bem, 1990). For example, homotypic continuity reflects the expression of similar behaviors or attributes over time, whereas heterotypic continuity is characterized by coherence in underlying organization or meaning of behaviors over time. In reflecting another form of continuity, the operation of hierarchical motility in which processes of past organization are carried over into qualitatively new systems may serve to progressively limit possibilities for future change over time (i.e., canalization; Gottlieb, 1991; Waddington, 1957). Likewise, even broad concepts reflecting change and discontinuity indicate that there are many possible pathways to normal and abnormal development. As we noted earlier, multiple pathways may

merge to lead to similar outcomes (i.e., equifinality), or similar pathways at one point in time may diverge into very different outcomes (i.e., multifinality).

However, the pathways model is relatively new and leaves many questions for future research on interparental discord and child development. At a minimum, prospective longitudinal research is essential to begin to identify pathways of development. For example, retrospective research designs readily overestimate causal relations between predictors and outcomes (Cowan et al., 1996). Longitudinal research designs based on multiple times of assessment are relatively rare in the study of relations between interparental discord and child development (Grych & Fincham, 2001). The identification of trajectories of development attributed to interparental discord is complicated by the fact that marital conflict is only one of the many possible risk or compensatory influences on children's development, as reflected by assumption of an ecological transactional framework (Cicchetti & Lynch, 1993).

FUTURE RESEARCH DIRECTIONS

Throughout our discussion of current theory and research, we have attempted to address specific substantive gaps in the literature and their implications for future research. However, it is also important to step back and contemplate broader thematic issues to formulate an integrative agenda for future research. Toward this goal, the remainder of this chapter is devoted to sketching some rough empirical blueprints for future research.

Multilevel, Multivariate Models of Interparental Conflict

The past decade has witnessed unprecedented progress in advancing more complex, multivariate models of interparental and child functioning that increasingly consider the interplay among multiple factors and interrelationships over time in identifying the causal processes that underlie child development (Davies, Harold, et al., 2002; Harold, Shelton, Goeke-Morey, & Cummings, 2004). The ultimate goal of the research program over the past decade has been to characterize how and why, and for whom and when, interparental conflict is associated with greater risk for psychological problems (E. M. Cummings & Davies, 2002). Although substantial progress has been made in empirically testing direct and indirect path models of inter-

parental conflict, the general failure to simultaneously examine these pathways raises important questions about how they might jointly operate in accounting for associations between interparental conflict and child maladjustment. Moreover, our integration of risk and protective frameworks within a broader ecological-transactional model generates unanswered inquiries about the nature of the interplay between interparental conflict and the multidimensional, multilayered constellation of contextual factors (e.g., familial, ecological, child). Thus, to advance a well-articulated account of pathways of interparental conflict in a biopsychosocial matrix, explicating the joint effects of interparental conflict and other contextual factors within mediator, moderator, and additive models will remain a central undertaking in future research (Baron & Kenny, 1986; Holmbeck, 1997, 2002).

In further broadening the scope of inquiry, greater conceptual and methodological sophistication will also be needed to fully capture the heterogeneity and diversity across individuals and development in the nature, operation, and sequence of processes underlying pathways between interparental conflict and child adjustment. On the one hand, moderator models provide a useful tool for identifying the intra- and extraorganismic characteristics that increase and decrease the vulnerability of children from high-conflict homes. Yet, at this relatively early stage of research, simply ending the inquiry at cataloguing the moderating effects of a particular attribute is conceptually unsatisfying without seeking to understand why individuals with certain characteristics or experiences evidence greater vulnerability. Addressing the question of why some individuals are more or less vulnerable to interparental conflict will require that moderator effects be followed up with specific applications of mediator models. For example, after identifying that adolescent girls exhibited significantly greater vulnerability to interparental conflict than their male counterparts, Davies and Lindsay (2004) sought to identify why adolescent gender moderated interparental conflict. Consistent with predictions derived from the gender intensification hypothesis (Davies & Lindsay, 2001; Hill & Lynch, 1983), the results indicated that girls' tendencies to experience greater levels of communion partially accounted for their greater vulnerability to interparental conflict. Such designs have the potential to provide broader conceptual and analytic blueprints for identifying the more proximal processes that explain why the impact of interparental conflict on children varies as a function of extrafamilial, familial, or other child attributes (also see Barrera et al., 1995).

On the other hand, the modest to moderate magnitude of mediational pathways in many family process models underscores the importance of identifying sources of individual differences in mediating processes. Thus, supplementing mediator tests with moderator analyses will likely prove useful in identifying the specific child, familial, and extrafamilial characteristics that may magnify or diminish the strength of mediational pathways (see Path 4 in Figure 3.1). For example, the emotional security theory postulates that the nature and strength of mediational pathways between interparental conflict, child emotional insecurity, and child maladjustment vary depending on the operation of processes in the larger family system (e.g., instability, cohesion, expressiveness). In supplementing tests of the mediation with moderator analyses at each link in the mediational chain, recent research supported these predictions by demonstrating that forms of family adversity were potentiating factors and forms of family harmony were protective factors in these mediational pathways (Davies, Harold, et al., 2002). Taken together, newly emerging research questions will challenge researchers to specify more complex blends of moderator and mediator models (Baron & Kenny, 1986; Kerig, 1998; Sturge-Apple et al., in press).

By the same token, these complex variable-based approaches often require extremely large sample sizes to obtain reliable estimates of parameters. Therefore, some of these statistical applications may not be feasible for researchers. Moreover, given that variable-based approaches are specifically designed to chart the average expectable relations between family processes and child adaptation, they run the risk of failing to sufficiently distinguish and capture the integrity and uniqueness of individual dimensions of family and child functioning. Because identifying individual differences in the organization of intraindividual and child functioning is a central aim in developmental psychopathology (Cicchetti & Rogosch, 1996; Richters, 1997), a complementary methodological direction is to expand and refine strategies for capturing the larger organization of child and family functioning at a pattern-based level. Specifically, future research may be able to fruitfully build on the foundational application of pattern-based measurement batteries (e.g., observational coding) and analytic models (e.g., latent class, cluster, or q-factor analyses) for identifying organizational patterns at the family level of functioning (e.g., Belsky & Fearon, 2004; Davies, Sturge-Apple, et al., 2004; P. K. Lindahl, 2001; O'Connor et al., 1998), child coping (E. M. Cummings, 1987; Davies & Forman, 2002; El-Sheikh et al., 1989), and child adjust-

ment (e.g., Grych, Jouriles, Swank, McDonald, & Norwood, 2000).

Protection, Resilience, and Competence

A trade-off of the predominant empirical focus of identifying the negative psychological sequelae of children from high-conflict homes has been the relative neglect of the study of children who manage to develop normally or even thrive in the face of interparental adversity (E. M. Cummings & Davies, 1994a). Thus, a broad recommendation for future research is to more fully complement the models of risk and vulnerability with the study of protection and resilience. Fully integrating the study of interparental conflict in frameworks of resilience and protection will hinge on corresponding challenges of precisely identifying incidences of resilience and the underlying factors and processes that account for child adaptation in high-conflict homes. In identifying resilient individuals, conceptualizations and assessments must be able to capture the dynamic nature of resilience, with particular recognition that some resilient children may experience bouts of considerable problems over time (Luthar & Cicchetti, 2000). Conclusions about resilience must also be sensitive to the multidimensional nature of resilience, as some children may demonstrate competence in some domains but psychopathology in other domains (Kaufman, Cook, Arny, Jones, & Pittinsky, 1994; Luthar, 1991).

After successfully meeting the challenge of identifying resilient individuals from high-conflict homes, the next step is to further delineate the protective factors and mechanisms that contribute to child competence despite exposure to destructive interparental conflict. Taxonomies that distinguish between various forms of protective effects are valuable tools in precisely characterizing how a given factor might contribute to adaptation (Luthar, 1993; Luthar & Cicchetti, 2000; Luthar et al., 2000). For example, an *ameliorative protective effect* diminishes, but does not completely offset, the potency of the vulnerability associated with interparental conflict. Conversely, a *neutralizing protective effect* is even more pronounced in the sense that marital conflict is benign at high levels of the protective factor. Thus, associations between interparental conflict and child psychological problems, which are robust at low levels of the protective factor, actually evidence a negligible relationship at high levels of the protective factor. Alternatively, *enhancing protective effects* occur when higher levels of interparental conflict are actually associated with

less symptomatology (or better adjustment) despite having harmful effects at low levels of the protective factor.

Although the search for protective factors has proceeded as if the concept were synonymous with inherently positive characteristics, adverse or stressful factors can also have protective effects in models of interparental conflict. Challenge models, which follow the assumption that growth results from adversity, specify that stressful conditions, especially in small or moderate doses, may actually have “steeling effects” that serve to enhance coping and adjustment and inoculate individuals against subsequent psychological insult (Garmezy, Masten, & Tellegen, 1984; Rutter, 1987). By extension, exposure to destructive interparental conflict may trigger children to develop more effective skills for coping and adjusting to adversity if bouts of conflict are relatively infrequent. However, in spite of robust analogues in medicine (e.g., vaccines), little attention has been paid to this possibility in the interparental literature.

Specification of Process: Multiple Levels of Analysis

Although current conceptualizations and future theoretical refinements will continually challenge researchers to build on existing measures and analyses of children’s emotional, social-cognitive, behavioral, and coping reactions to interparental conflict (Cummings et al., 2001), it is also important to note that several domains of risk processes are virtually unstudied. For example, very little is known about the physiological, neurobiological, and neuropsychological functioning of children from high-conflict homes (see “Diversity in the Operation of Risk Processes in Direct Path Models” section for more details). Corresponding gaps in knowledge also exist in the consideration of child functioning in the context of successive developmental or stage-salient tasks. Accordingly, a key challenge is to integrate these multiple systems of child functioning within theories and empirical tests of child coping and adjustment (e.g., El-Sheikh, 1994; El-Sheikh et al., 2001; Katz & Gottman, 1997). For example, in the emotional security theory (Davies, Harold, et al., 2002), managing concerns about emotional security requires considerable expenditure of biopsychosocial resources (e.g., attention, physiological resources, affect, thought processes, actions). Difficulties preserving security are theorized to alter and disrupt children’s capacities to marshal physical and psychological resources and maintain homeostasis through efficient resource allocation. Thus, consistent with other models of family discord (e.g., Cicchetti & Rogosch, 2001a, 2001b), child concerns

about insecurity in homes marked by discord or violence are posited to be accompanied by irregularities in neurobiological and neuropsychological functioning and reactivity to subsequent stress. As part of this constellation of difficulties in resource regulation and allocation, children experiencing difficulties with insecurity may not have sufficient resources to successfully resolve significant developmental tasks and goals.

Future research will also need to develop strategies for simultaneously examining multiple levels of analysis in children’s response processes. As we have seen, pattern-based approaches to studying children’s higher-order patterns of coping and emotional security offer promise in understanding how child coping processes contribute to the development of psychopathology in high-conflict homes (E. M. Cummings, 1987; E. M. Cummings & Cummings, 1988; Davies & Forman, 2002; El-Sheikh et al., 1989; Maughan & Cicchetti, 2002). As the field advances, inclusion of multiple risk processes in models of interparental conflict will also permit tests of the relative viability of child coping and responses to interparental conflict derived from alternative theories. Over a decade ago, Fincham and colleagues (1994) cogently argued that testing process models in relation to alternative hypotheses derived from other conceptualizations provides significantly more conceptual yield than testing predictions in relation to the null hypothesis. Yet, despite this call, virtually no studies have simultaneously compared the efficacy of risk processes generated from different theories (Davies, Harold, et al., 2002). With the unprecedented theoretical advances in the area over the past decade, the urgency of testing the relative efficacy of different risk processes in future studies cannot be understated.

Interparental Conflict and Child Functioning in Abnormal Contexts

Guided by the assumption that little is known about risk in normal community families, Cowan and colleagues (1996, p. 31) aptly noted, “The frequency of distress in nonclinical families is (unfortunately) large enough to justify concerted attempts to apply risk paradigms to studies of normal family adaptation.” Although this conclusion is applicable to many areas of developmental psychopathology, the opposite state of affairs actually exists in the interparental conflict literature. Rather than advancing developmental psychopathology models of interparental conflict through primary inclusion of high-risk samples, studies have overwhelmingly relied on community samples. Consequently, little is known about whether similar or differ-

ent processes and pathways involving interparental and child problems that have been identified in community samples operate for families who are experiencing considerable adversity or vulnerability. For example, although children exposed to severe interparental violence are as much as 7 times more likely to exhibit significant psychological problems than are children in the general population, progress in identifying processes and pathways underlying the exposure to interparental violence has been slow. Because little is known about how and why interparental violence increases child vulnerability to psychopathology, future research would do well to identify the unfolding mediating mechanisms and the potentiating and protective conditions that shape the multiplicity of pathways underlying associations between interparental violence and child maladjustment (Kitzmann et al., 2003). In supporting a broader foray into high-risk processes, inclusion of parent and child psychological problems in models of interparental conflict does appear to alter some process relationships between interparental and child functioning (e.g., Davies & Windle, 2001; Emery et al., 1999; Papp, Cummings, et al., 2004). However, because these studies have predominantly examined individual differences in psychological adjustment indices in normal or well-functioning samples, how interparental conflict processes operate across a broad spectrum of risk and clinical disorder is still not known.

Transactional Relationships between Interparental and Child Functioning

Although developmental psychopathology strongly emphasizes the active role of the child in the dynamic transactional interplay between the child and interpersonal contexts (Zigler & Glick, 1986), unidirectional designs continue to be geared toward understanding the impact of interparental conflict on child functioning (E. M. Cummings & Schermerhorn, 2003). Child effects models are thus crucial for understanding the dynamics of family processes as influences on child development. Research has long demonstrated that children respond to marital conflict with apparently agentic behavior, that is, mediation or other attempts to reduce marital conflict (e.g., J. S. Cummings et al., 1989). Children's coping with marital conflict, including perceived control and effortful behavior toward regulating the conflict, has been advanced as possibly ameliorating the effects of marital conflict on children (Kerig, 1998, 2001; Rossman & Rosenberg, 1992).

However, due to the paucity of work on whether forms of child reactivity do more than help children feel more se-

cure about marital conflict, little is known about whether children's perceptions of agency or effortful behavior relate to changes in interparental conflict over time. To address this knowledge gap, Schermerhorn, Cummings, and Davies (in press) reported that interparental conflict was not only concurrently linked with children's perceived agency as predicted by the emotional security theory, but perceived agency also predicted declines in interparental conflict over 1 year (E. M. Cummings & Davies, 2002; Davies & Cummings, 1994).

In another study, bidirectional analyses between adolescent adjustment and marital discord revealed that adolescent symptomatology predicted reductions in interparental conflict over time, whereas interparental conflict was associated with subsequent increases in adolescent symptomatology (Schermerhorn, Goeke-Morey, Mitchell, & Cummings, 2004). Given these promising findings, systematically tracing transactions between children and interparental conflict is likely to be a central direction for future research.

Charting Developmental Pluralism in the Context of Interparental Conflict

The increasing use of longitudinal designs over time will permit greater flexibility in charting the nature, correlates, origins, and sequelae of individual differences in developmental pathways in models of interparental conflict. Although it is important not to understate the advantages of well-designed cross-sectional and short-term longitudinal studies for many important research questions (Rutter, 1994), these designs cannot readily examine a central aim of developmental psychopathology: identifying interindividual differences in developmental pathways over time. Rather, reliably charting individual differences in slope, starting points, and end points of children or family trajectories will require future longitudinal research to contain a minimum of three repeated measures of key constructs (Willett, Singer, & Martin, 1998). For example, using multiwave data in analytic techniques such as hierarchical linear modeling and latent growth models will specifically permit researchers to examine how interparental conflict processes factor into understanding the nature, origins, correlates, and sequelae of individual differences in child adjustment trajectories (e.g., E. M. Cummings et al., 2001; Windle, 2000). Moreover, even more recent analytic models no longer make the tacit assumption that individual differences in developmental pathways are continuously distributed around a single trajectory of functioning over

time. Instead, such techniques as latent class growth analysis are specifically designed to parsimoniously identify the number and nature of distinct developmental trajectories of functioning and, as a result, permit analyses of the antecedents, correlates, and sequelae of these trajectories (Muthen & Muthen, 2000; Shaw, Gilliom, Ingoldsby, & Nagin, 2003). Thus, these analytic tools are likely to be particularly valuable in beginning to elucidate the interplay among interparental risk factors, risk processes, and multiple trajectories of child functioning.

Prevention and Public Policy Implications

The developmental psychopathology perspective, with its emphasis on relationships between pathways of development and adjustment, provides a clear conceptual rationale for advocating for prevention as an alternative to intervention for children's adjustment problems due to marital discord (Cicchetti & Cohen, 1995; E. M. Cummings et al., 2000). Also advocating for prevention approaches, problems of interparental discord are likely to be much more amenable to positive influence before the conflict process becomes escalated and highly negative (E. M. Cummings & Davies, 1994a). However, it is essential that optimal prevention efforts be closely informed by research, including the latest findings on marital conflict from the perspective of the children. Our literature review indicates that a relatively comprehensive process-oriented model for marital conflict and its effects on children and families, grounded in etiological theory, is available and merits careful consideration in formulating prevention and intervention directions. Although programs for enriching and enhancing marriages, especially premarital programs for new marriages, are widespread and have been proposed at least since the 1930s, there has been little inclusion of research-based conclusions or systematic and long-term evaluation of program effectiveness in most community-based programs.

The most extensively documented program for couples is the Prevention and Relationship Enhancement Program (Markman & Floyd, 1980), based on the notion that couples' deficits in communication and conflict resolution skills lead to marital distress (Markman, Jamieson, & Floyd, 1983). Although evidence for positive effects has accumulated (Markman, Renick, Floyd, Stanley, & Clements, 1993), support is not consistently found (van Widenfelt, Hosman, Schaap, & van der Staak, 1996), findings are relatively modest in long-term follow-ups, and implications for children are not evaluated. Other programs have addressed marital conflict issues in familywide psy-

choeducational programs (e.g., Positive Parenting Program; Sanders, Markie-Dadds, Tully, & Bor, 2000), but programs focusing on marital conflict and children have been minimally informed, at best, by the comprehensive model for processes and pathways associated with child maladjustment outlined in the present review. Programs have also been designed for interparental conflict and children, but primarily for children of divorce (Pedro-Carroll & Cowen, 1985; Shifflett & Cummings, 1999; Stolberg & Mahler, 1994), with rare exceptions (see Lindsay, Davies, & Pedro-Carroll, 2001). Finally, more rigorous tests of programs in this area are also needed, including random assignment to groups, treatment fidelity assessments, manualization of programs, adequate control groups, and long-term follow-ups concerning the effects on both parents and the children.

From a public policy perspective, translating research findings into viable prevention programs holds great promise in helping families and children. Efficacious prevention efforts have the potential to reach far more families than traditional clinical services in a more economically efficient manner. Moreover, given that it is more difficult for individuals to reclaim normal trajectories of development with longer histories of maladaptive experiences, prevention programs or, minimally, early intervention programs have greater potential to yield more positive outcomes than programs that target families with severe or chronic problems.

CONCLUSION

In conclusion, the emergence and growth of developmental psychopathology as a science over the past 2 decades has been accompanied by advances in the interparental conflict literature toward identifying the unfolding pathways between interparental characteristics, risk processes, and children's outcomes in the broader context of biopsychosocial factors. Developmental psychopathology, with its original armamentarium of concepts and principles (e.g., multiple pathways, risk and protective frameworks, multi-level processes), has been a central heuristic for a second generation of research designed to identify the moderating conditions and mediating mechanisms underlying the vulnerability of children from high-conflict homes (Margolin et al., 2001). Our attempt to further situate the study of interparental conflict within developmental psychopathology also illustrates the need for new research directions that examine interparental conflict within even more sophisti-

cated multilevel, multivariate frameworks that capture the multiple pathways that evolve from the transactional interplay between interparental and child functioning. With the recent conceptual, methodological, and analytic advances noted throughout this chapter, it is hoped that a new generation of research will emerge that advances the integration of the interparental conflict literature in the discipline of developmental psychopathology.

The notion of an average expectable environment for promoting normal development proposes that there are species-specific ranges of environmental conditions that elicit normative developmental processes (Hartman, 1958). Humans, like all other species, develop within a “normal range” when presented with such an average expectable environment (Dobzhansky, 1972; Gottesman,

1963). For infants, the expectable environment includes protective, nurturant caregivers and a larger social group to which the child will be socialized, whereas for older children, the normative environment includes a supportive family, a peer group, and continued opportunities for exploration and mastery of the environment. Variations within this range of environments afford opportunities for individuals to dynamically engage in the construction of their own experiences (Scarr & McCartney, 1983). When environments fall outside the expectable range, normal development is impeded.

Grants from the Office of Child Abuse and Neglect, the National Institute of Drug Abuse, the National Institute of Mental Health, and the Spunk Fund, Inc., supported our work on this chapter.

Elaborating on the role of the environment in the expression of genes, Scarr (1992, 1993) asserted that infants and children might be genetically preadapted to respond to a specific range of environmental experiences. Furthermore, Scarr added that individual developmental differences when in the context of the expectable environment are largely the result of genotypic differences. Thus, Scarr conceptualized the environment as providing a specific range of conditions that allow for the phenotypic expression of genes. Gottlieb (1991) has further contributed to our understanding of gene-environment interactions by pointing out that genetic activity does not act in isolation to produce either finished physical traits or complex individual personality characteristics. Instead, a systems view of development (Gottlieb, 1991, 1992) conceptualizes human development as hierarchically organized into multiple levels that have mutual influence on each other (Cicchetti & Cannon, 1999; Cicchetti & Lynch, 1995; Gottlieb, 1991, 1992; F. D. Horowitz, 1987). Bidirectional effects are expected to occur from the top down as well as from the bottom up among genetic activity, neural activity, behavior, and the environment (Cicchetti & Tucker, 1994). These bidirectional effects among levels of the system result in a probabilistic conceptualization of epigenetic development. Therefore, no single component of the system can “cause” development; rather, it is the mutual relationship among components of the developmental system that brings about development and phenotypic expression (Cicchetti & Cannon, 1999).

In the past decade, our understanding of the role of the environment and its interaction with genes has been further clarified, whereby reciprocal coactions between the environment and the individual have resulted in differential expression of genetic material (Cicchetti, 2002; Eisenberg, 1995; Kandel, 1998, 1999). Environmental conditions may interact with an individual’s genetic makeup to alter processes such as the timing of the initiation of transcription and translation for a specific gene, the duration for which it does so, or whether the gene will ultimately be expressed. Thus, a new ecological level can be added to our systems model to acknowledge the distinction between genetic code and genetic expression, as well as how interactions with the environment at each level may contribute to our understanding of probabilistic epigenesis (Gottlieb, 1992).

So now we come to the question of what conditions fall within the range of the human average expectable environment to promote normal development and, alternatively, what happens to development when there are severe disturbances in such an environment. Consistent with a develop-

mental psychopathology perspective, the examination of maladaptive and psychopathological development can elucidate the underlying mechanisms of normal development (Cicchetti, 1984, 1990a, 1990b, 1993; Rutter, 1986; Sroufe, 1990; Werner, 1948). In typical development, the component developmental systems may be so well integrated that it is difficult to determine how normal functioning is dependent on this integration (Cicchetti & Sroufe, 1976). From a systems perspective, the environment also exists as a component of the developmental system. Thus, when the conditions of an average expectable environment are available, the manner in which its components interact is also challenging to identify.

As proffered by Cicchetti (2003, p. 833), “When there is a clear perturbation or deficit in a component system, examination of how that atypicality relates to the organization of other component systems can reveal important information regarding the interdependence of components that are not apparent under normal conditions.” Thus, “experiments of nature,” such as being raised in a maltreating home, enable us to isolate components of the developmental system and elucidate the structural organization of the normal system. Through the examination of child maltreatment, which may represent the greatest failure of the environment to provide opportunities for normal development, we can begin to identify the range of conditions that encompass the average expectable environment. Moreover, we may come to an understanding of how serious deviations from this range may affect organism-environment coactions that play important roles in the emergence and timing of normal developmental change.

The goals of this chapter are to provide a review of child maltreatment, updating our chapter from the prior edition of these volumes (Cicchetti & Lynch, 1995). Although a thorough review of the literature is presented, the focus of this chapter is on the developments that have occurred in the field since 1995. Of particular salience is the growing contribution of neurobiological and genetic research to the study of child maltreatment, such that ontogenic development can be considered from both psychological and neurobiological perspectives. We then address how these recent advances may inform prevention and intervention efforts. Finally, we offer recommendations for future research and social policy initiatives.

EPIDEMIOLOGY

It is critically important to examine epidemiological estimates of child maltreatment, as the criteria used to define

maltreatment affect the incidence and prevalence rates of child abuse and neglect, as well as the national services that are implemented to address this important societal issue. Since the passing of the Child Abuse Prevention and Treatment Act (CAPTA) in 1974, the National Center on Child Abuse and Neglect (NCCAN) was established as a federal research center aimed at understanding the causes and preventing the occurrence and negative consequences of child maltreatment. Since that time, National Incidence Studies (NIS) have been compiled by the NCCAN to provide a comprehensive source of information regarding the epidemiology of child abuse and neglect in the United States (U.S. Department of Human and Health Services [NIS-I], 1981; [NIS-II], 1988; [NIS-III], 1996). The 1988 amendments to the CAPTA directed the U.S. Department of Human and Health Services (USDHHS) to establish a national data collection and analysis program. Consequently, the National Child Abuse and Neglect Data System (NCANDS) has published the most recent national reports on child maltreatment. According to their report, an estimated 896,000 children in the United States were victims of child abuse or neglect in 2002, translating into a rate of victimization that equals 12.3 per 1,000 children in the national population (USDHHS, 2002).

Furthermore, an estimated 1,400 fatalities were reported in 2002, representing 1.98 children per 100,000 in the national population (USDHHS, 2002). Fatality, as defined by the NCANDS system, refers to the death of a child caused by an injury resulting from abuse or neglect, or where abuse or neglect were contributing factors. Additional studies, however, report that as many as 50% to 60% of deaths resulting from abuse or neglect are not reported (Crume, DiGuseppi, Byers, Sirotnak, & Garret, 2002; Herman-Giddens et al., 1999), citing child neglect as the most underrecorded form of fatal maltreatment.

During 2002, 60.5% of documented child maltreatment victims experienced neglect, 18.6% were physically abused, 9.9% were sexually abused, and 6.5% were emotionally or psychologically maltreated. Furthermore, almost 20% were associated with "other" types of maltreatment based on specific state and law policies. Regarding the victims of abuse, children had the highest rates of victimization in the period from birth to 3 years, at 16 per 1,000 children, and girls were slightly more likely to be victims than boys. Among ethnic groups, American Indian and African American children had the highest rates of victimization (21.7 and 20.2 per 1,000 children, respectively), compared to the rate of victimization among European Americans (10.7 per 1,000 children). Reports on the perpetrators of maltreatment indicate that more than 80%

of perpetrators were parents; other relatives accounted for 7%, and unmarried partners of parents accounted for an additional 3% (USHDDS, 2002); women, mostly mothers, were a larger percentage of perpetrators (58%) than men (48%). Strikingly, children from single-parent families were at increased risk for abuse or neglect compared to children from two-parent homes (27.3 versus 15.5 per 1,000 children, respectively; USDHHS, 1996). Moreover, children from families whose incomes were less than \$15,000 were 22 times more likely to experience some form of maltreatment than were children from families whose incomes exceeded \$30,000 annually.

An estimated 2.6 million referrals of abuse or neglect, concerning nearly 4.5 million children, was received by Child Protective Services agencies in 2002. More than 66% of those referrals were accepted for investigation or assessment, and approximately 30% of the reports included at least one child who was found to be a victim of child abuse or neglect. Although 61% of the reports filed were found to be "unsubstantiated," evidence demonstrates that significant psychosocial maladjustment accompanies both unreported and unsubstantiated instances of child maltreatment (B. Drake, 1996). Given the heterogeneity contained among unsubstantiated reports of child maltreatment, caution should be taken against accepting the notion that unsubstantiated means that maltreatment did not occur (Barnett, Manly, & Cicchetti, 1993; Cicchetti & Toth, 2003; B. Drake, 1996).

In light of the alarming epidemiological rates of maltreatment, which likely underestimate the prevalence of child abuse and neglect in our country, one might wonder what social policy actions are being taken to address this serious national problem. On the national level, approximately 59% of victims and 31% of nonvictims received services as a result of investigation or assessment in 2002. Additionally, children who were prior victims of maltreatment were more than 80% more likely to receive services than first-time victims, as were children with multiple types of maltreatment in comparison to children with only one type of recorded maltreatment. To respond to the issue of receipt of services, the newly amended and reauthorized Child Abuse Prevention and Treatment Act, the Keeping Children and Families Safe Act of 2003 (PL 108-36), now requires states to refer abused and neglected young children to the Early Intervention Program (known as Part C of the Individuals with Disabilities Education Act; Dicker & Gordon, 2004). This revision was implemented to extend the act's original goal of child safety to focus on child well-being and permanency. The new referral requirement provides a rich entitlement for services for children under 3

years of age involved in substantiated cases of abuse or neglect and their families. Services include physical, occupational, and special therapies, psychological testing, special instruction, adaptive technology devices, nursing services, nutrition counseling, and transportation. Additional family support services include training, counseling, support groups, home visits, and special instruction to enhance child development. Practical challenges of initiating the referral, obtaining parental consent, and securing parental involvement to ensure the receipt of services must be met so that the potential of the CAPTA revision to increase the receipt of services to maltreated children is realized.

ISSUES OF DEFINITION

Despite widespread agreement that child maltreatment is a serious societal problem, placing children's welfare and normal development in jeopardy, there has been a long history of discordance among researchers, lawmakers, and clinicians on what constitutes maltreatment and how it should be defined (J. L. Aber & Zigler, 1981; Barnett et al., 1993; Besharov, 1981; Cicchetti & Manly, 2001; Cicchetti & Rizley, 1981; Emery, 1989; Juvenile Justice Standards Project, 1977). Contributing to the lack of consensus is a debate regarding whether it is realistic to expect professionals from various domains to agree on a single definitional approach given the widespread differences between fields in the purpose and utilization of such a definition. For example, the medical-diagnostic definition of maltreatment revolves around the individual abuser (J. L. Aber & Zigler, 1981) and focuses on overt signs of maltreatment. This approach tends to highlight physical abuse while minimizing psychological maltreatment. The legal definition focuses on demonstrable physical and emotional harm to children, particularly that which would be useful as evidence for prosecution (Juvenile Justice Standards Project, 1977). In contrast, parental acts and society's role in perpetuating maltreatment are important for the sociological definition, and evidence of environmental and familial contributors to the occurrence of maltreatment are necessary elements of the ecological approach (Cicchetti & Lynch, 1993; Cicchetti, Toth, & Maughan, 2000). Many researchers have asserted that the definition of maltreatment should focus on specific acts that endanger the child in some way (Barnett, Manly, & Cicchetti, 1991; Barnett et al., 1993; Cicchetti & Barnett, 1991b; Zuravin, 1991). This type of definition

would allow researchers to concentrate on the identifiable behaviors that compromise the child's maladaptive caretaking environment.

Even within the domain of research, however, a number of complexities contribute to the lack of consensus regarding the definition of maltreatment employed by various investigators, making comparability across studies difficult to achieve (Barnett et al., 1993). First, maltreatment is largely influenced by legal matters, as it is identified and defined by social service systems, rather than by researchers or mental health professionals. Furthermore, there is not a clear standard regarding the distinction between acceptable parental disciplinary practices and maltreatment (M. M. Black & Dubowitz, 1999; Cicchetti & Lynch, 1995); there is a lack of agreement on whether child maltreatment should be defined based on the actions of the perpetrator, the effects on the child, or a combination of the two (Barnett et al., 1991, 1993); and there is debate as to whether parental intent should be considered. These issues raise additional methodological concerns, as it is a greater challenge to measure parental intent than parental behavior. Moreover, linking maltreatment to child outcome leads to difficulty in separating child maltreatment from its subsequent sequelae (Barnett et al., 1991; Cicchetti & Manly, 2001; McGee & Wolfe, 1991).

Based on the wide range of challenges faced by maltreatment researchers, one clearly cannot expect all who study maltreatment to use the same methodology for operationalizing child abuse and neglect. However, all approaches must be derived from clear operational definitions of maltreatment such that replication may be possible across investigations (Cicchetti & Manly, 2001). Despite the challenges facing maltreatment researchers, four general categories of child maltreatment have been distinguished from one another and are widely accepted:

1. *Sexual abuse* refers to sexual contact or attempted sexual contact between a caregiver or other responsible adult and a child, for the purposes of the caregiver's sexual gratification or financial benefit.
2. *Physical abuse* refers to injuries that have been inflicted on a child by nonaccidental means.
3. *Neglect* refers to failure to provide minimum standards of care as well as adequate supervision.
4. *Emotional maltreatment* refers to persistent and extreme thwarting of a child's basic emotional needs.

Additionally, McGee and Wolfe (1991) offered a slightly different conceptualization for emotional maltreatment, which they called psychological maltreatment, which en-

compasses both psychologically abusive and psychologically neglectful experiences. Although each of these subtypes represent distinct deviations from the average expectable caregiving environment, it is well documented that they rarely occur in isolation from each other (Cicchetti & Manly, 2001). In actuality, the majority of maltreated children experience more than one subtype of maltreatment, presenting significant challenges for clinicians and researchers who strive to understand the unique effects of each type of maltreatment experience on development.

Responding to the need for a detailed classification system for maltreatment, Cicchetti and Barnett (1991b; see also Barnett et al., 1993) developed a multidimensional nosological system for categorizing children's maltreatment histories. In recognition of the need to include developmental considerations in assessing maltreatment, the Maltreatment Classification System (MCS; Barnett et al., 1993) not only provides operational definitions of maltreatment subtypes, with inclusion and exclusion criteria and exemplars of each of the five levels of severity for each subtype, but also includes measurement of the onset, frequency, and chronicity of each subtype, the developmental period(s) during which each subtype occurred, the severity of each subtype, and the perpetrator(s) of each subtype. This comprehensive assessment across and within dimensions of maltreatment has allowed for a more detailed understanding of the maladaptive developmental pathways associated with children's maltreatment experiences. For example, through the utilization of the MCS, the interaction between severity and frequency of maltreatment has emerged as a significant predictor of maladaptation (Manly, Cicchetti, & Barnett, 1994). Moreover, the chronicity of maltreatment has been identified as a robust dimension in predicting peer rejection and aggression (Bolger & Patterson, 2001; Bolger, Patterson, & Kupersmidt, 1998). The timing of maltreatment was noted as an important factor relating the impact of maltreatment on self-perceptions and relationships with peers (Bolger et al., 1998). Additionally, an investigation specifically examining the contributions of developmental timing and subtype to child adaptation highlighted the interaction of the severity of particular maltreatment subtypes with the developmental period during which the maltreatment began in differentially predicting internalizing and externalizing symptomatology (Manly, Kim, Rogosch, & Cicchetti, 2001). In particular, the impact of chronicity was underscored by noting that chronic maltreatment, especially with onset in the infancy-toddlerhood or preschool period, was linked with more maladaptive outcomes.

Apart from the significant advances in the classification of child maltreatment, further methodological challenges face researchers regarding the collection of information on which to base classification decisions. Of particular concern are the challenges associated with the identification and operationalization of child neglect. The "neglect of neglect" has been acknowledged in the literature for quite some time (Wolock & Horowitz, 1984), yet child neglect continues to be a relatively understudied aspect of maltreatment. Nonetheless, the experience of neglect should not be ignored as child neglect is consistently the most commonly reported form of child maltreatment in the United States (USDHHS, 2002), with consequences that can often be as severe as those associated with physical and sexual abuse (cf. Hildyard & Wolfe, 2002; Trickett & McBride-Chang, 1995). The pervasive nature of neglect, however, makes research on the effects of neglect, in isolation from other abuse experiences, particularly difficult. Unlike physical or sexual abuse, which often have overt physical consequences that are usually incident-specific and clearly identifiable, neglect is often a chronic experience that leaves little visible evidence and has an accumulating effect over time. Moreover, physical neglect, referring to the failure to adequately meet the physical needs of children, is closely related to poverty, so that it is increasingly hard to identify neglect over and above economic disadvantage.

An additional methodological concern relates to the strategy utilized to assess maltreatment. For example, self-report (by the perpetrator and/or victim) has frequently been used to ascertain the occurrence of maltreatment, as have observational paradigms and the use of official Child Protective Services reports (e.g., Dodge, Pettit, & Bates, 1997; Egeland & Sroufe, 1981; Manly et al., 1994). Each of these methods has a number of strengths and weaknesses that must be considered when offering interpretation of results based on such operational definitions. Furthermore, Newcomb and Locke (2001) assert that the methodologies of much of the existing research are marked by fundamental weaknesses, such as using case status alone to define subjects, adopting a dichotomous perspective of maltreatment without conceptualization on various dimensions and continua, and using operational definitions that fail to differentiate among maltreatment subtypes. Although the use of adult retrospective reports of maltreatment experienced as a child to identify and define maltreatment has received heavy criticism for its possible lack of validity (Widom, 1989), standardized assessments such as the Child Trauma Questionnaire have been developed as reliable and valid means

for collecting retrospective data (Bernstein, Ahluvalia, Pogge, & Handelsman, 1997; Bernstein et al., 1994; Goodyear, Newcomb, & Allison, 2000; Rosen & Marton, 1998). Whenever possible, the research reviewed in this chapter focuses on that which has been the product of psychometrically accepted methodology.

Etiology of Maltreatment

Early views on the development of maltreatment emerged from a “main effects” perspective, in which it was believed that single risk factors such as poverty, parental psychopathology, or a personal history of maltreatment could alone provide an etiological account for the occurrence of child maltreatment (Cicchetti & Toth, 1995; Gelles, 1991). However, these unidimensional views on the etiology of child maltreatment soon gave way to more complex models, as it became clear that no single risk factor or set of risk factors would explain the development of maltreatment (Belsky, 1980; Cicchetti & Lynch, 1995; Cicchetti & Rizley, 1981). Emerging from the ecological-developmental theory set forth by Bronfenbrenner (1979), current theories acknowledge the contributions made by transacting factors operating at environmental, contextual, familial, and individual ecologies (Belsky, 1980, 1993; Cicchetti & Lynch, 1993; Cicchetti & Rizley, 1981; Garbarino, 1977; Parke & Collmer, 1975; Wolfe, 1991).

Applying Bronfenbrenner’s (1979) theory of human development, the etiological model proposed by Belsky (1980) initiated dramatic changes in the conceptualization of child maltreatment, as it necessitated the consideration of the broader environment in which maltreatment occurs. According to Belsky, child maltreatment is a social-psychological phenomenon that cannot be understood in isolation from the community and the culture within which the family and the individual are embedded. As such, his model contains four levels of analysis: the *macrosystem*, including the cultural beliefs and values that contribute to and influence child maltreatment; the *exosystem*, including aspects of the community to contribute to the incidence of maltreatment; the *microsystem*, including factors within the family that contribute to the occurrence of maltreatment; and *ontogenic* development, including factors within the individual that are associated with being a perpetrator of maltreatment. Given that proximity to the individual increases with each subsequent level of the ecology (from the macrosystem to the ontogenic context), Belsky further highlighted that risk factors at ecological levels that are closer to the individual exert a more direct influence on an individual’s development. Moreover, interactions exist be-

tween all levels of the ecology, contributing to and influencing the occurrence of child maltreatment.

Cicchetti and Rizley (1981), drawing on the work of Sameroff and Chandler (1975), introduced additional elements to the etiological model of maltreatment by proposing a transactional model. This model focused on the reciprocal interactions of the environment, the caregiver and the child, which together contribute to the outcomes of child development. An important distinction was made between two classes of risk factors: those that are potentiating, thereby increasing the risk for maltreatment, and those that are compensatory, which decrease the risk for maltreatment. Additionally, a temporal dimension was added to distinguish between risk factors that are transient versus those that are enduring. By combining these categorical and temporal dimensions of risk factors, Cicchetti and Rizley proposed four classes of determinants for the occurrence of child maltreatment: enduring vulnerability factors, transient challengers, enduring protective factors, and transient buffers. This model conceptualized the risk for child maltreatment as probabilistic, proposing that the likelihood of maltreatment occurring is determined by the balance among risk and protective factors and processes (Cicchetti & Carlson, 1989).

Integrating the etiological models of Belsky (1980) and of Cicchetti and Rizley (1981), Cicchetti and Lynch (1993) proposed the ecological-transactional model of child maltreatment. By incorporating the ideas of the average expectable environment and probabilistic epigenesis into a broad integrative framework, this model explains how processes at each level of ecology exert reciprocal influences on each other and shape the course of child development (Cicchetti & Lynch, 1993). As such, potentiating and compensatory risk factors associated with maltreatment are present at each level of the ecology and can influence processes in the surrounding environmental levels. These dynamic transactions, which operate both horizontally and vertically throughout the levels of ecology, determine the amount of risk for maltreatment that an individual faces at any given time (see Figure 4.1). The levels of ecology most proximal to the child have the most direct impact on child development relative to the more distally located macrosystem. Although characterized by an overall pattern in which risk factors outweigh protective factors, there are infinite permutations of these risk variables across and within each level of the ecology, providing multiple pathways to the occurrence of maltreatment.

Ultimately, it is the child’s own ontogenic processes, as manifested by the particular developmental pathway that individuals engage in, that culminate in eventual adaptation

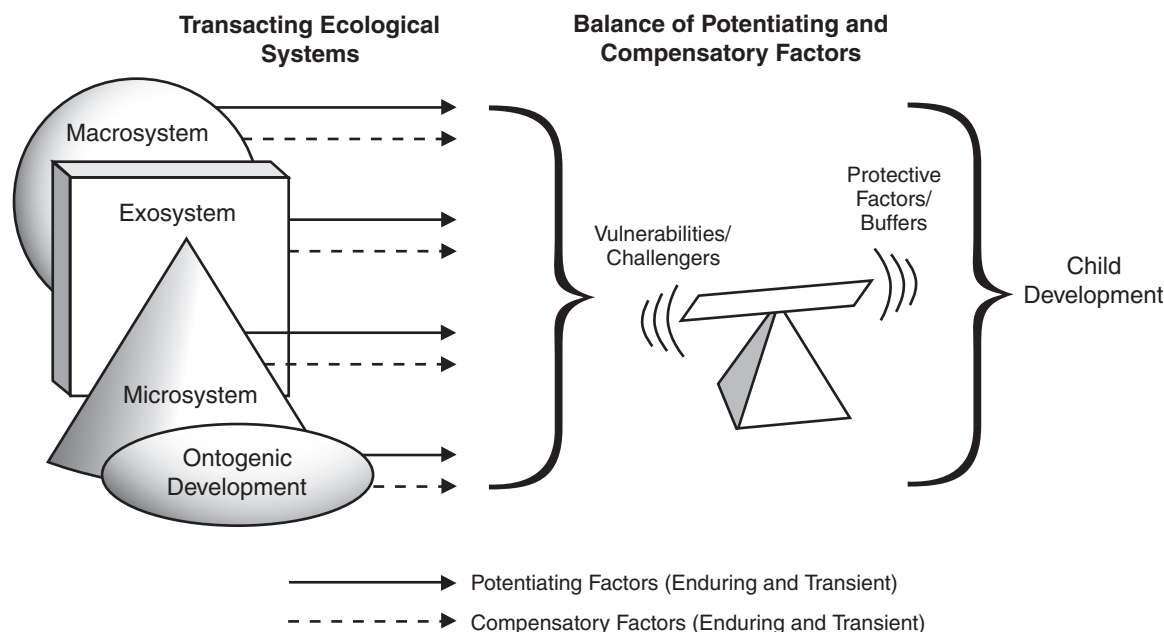

Figure 4.1 An ecological-transactional model of child maltreatment.

or maladaptation. The challenges or supports presented to children by the family, community, and society contribute to these ontogenic processes; however, children also play an active role in their organismic development as they respond to these influences and engage in the resolution of stage-salient developmental issues. In the case of child maltreatment, one could imagine how an increased presence of enduring vulnerability factors and transient challenges associated with maltreatment at each level of ecology contributes to unsuccessful resolution of stage-salient developmental tasks, setting the child on a pathway to maladaptive developmental outcomes and psychopathology (Cicchetti, 1990). The ecological-transactional model may also aid in providing an account for resilient outcomes. The presence of enduring protective factors may approximate features of the average expectable environment, thus allowing some children to display successful adaptation in the face of maltreatment.

The ecological-transactional model of child maltreatment (Cicchetti & Lynch, 1993) has remained the predominant etiological model in the field, albeit with some modifications as we have come to a better understanding of ontogenic development in neurobiological as well as psychological realms. As in our chapter in the prior edition of these volumes, this model serves as a heuristic for reviewing the literature on the consequences of child maltreatment and for addressing our questions regarding the impact of the failure of the average expectable environment on development. In particular, attention is focused on the emer-

gence of genetic and neurobiological research in the ontogenic development of maltreated children.

MACROSYSTEM

The macrosystem is the most broad and distal ecological level, referring to the set of cultural values and beliefs that are reflected in the community services offered by a society and that infuse individual and family lifestyles (Cicchetti & Lynch, 1995). Among the cultural phenomena of American society, social acceptance of violent crime was one of the earliest values to be identified for its possible contribution to child maltreatment. In comparison to other Western nations, the United States is characterized by an exceptionally high level of violent crime (M. Aber & Rapaport, 1994; Christoffel, 1990; Fingerhut & Kleinman, 1990; Lykken, 1993). Although the national rate of violent crime has decreased over the past decade, violent crime victimization remains a serious part of American culture, particularly in low socioeconomic status, urban areas. Highlighting the pervasive exposure of young people to violence, Finkelhor, Ormrod, Turner, and Hamby (2005) conducted a comprehensive national survey of violence, crime, and victimization experiences in a nationally representative sample of children ages 2 to 17 years. One in 8 children in this sample reported experiencing a form of child maltreatment, and 1 in 3 had been a witness to violence or other form of indirect victimization. Only 29% reported no

direct or indirect victimization (Finkelhor et al., 2005). Annual reports from the U.S. Department of Justice (2004) reveal that in 2003, U.S. residents age 12 or older experienced approximately 5.4 million crimes of violence. For every 1,000 persons age 12 or older, there occurred one rape or sexual assault, one assault with injury, and two robberies. Furthermore, about 1 in every 26 households in 2003 was either burglarized or had a member age 12 or older who was a victim of a violent crime committed by a stranger. Even more alarming, despite the drop in the national crime rate since 1993, juveniles have been consistently involved in 25% of serious violent victimizations annually over the past 25 years (U.S. Department of Justice, 2004).

Beyond attempts to identify specific cultural values such as the acceptance of violence that may characterize aspects of a generalized American culture, the application of culture to developmental psychopathology has shifted its focus toward identifying values within the multiple subcultures that constitute American society. The most recent approaches to cultural research are based on the premise that cultures that differ from the White, middle-class, mainstream cultural majority are legitimate adaptations to contextual demands and are valuable in their own right. This conceptualization thus moves away from deficit models, which had conceptualized these differences as deviation, maladaptation, or pathology that reflects deficits inherent in cultural values (Garica Coll, Akerman, & Cicchetti, 2000).

In addition to this new framework for approaching cultural influences, progress has been made in clarifying what is meant by the concept of culture. A plethora of definitions of culture have been offered, mainly focusing on the idea of culture as learned, as shared, and as the interpretive force that guides interactions among people (Korbin, 2002). Consistent with a developmental psychopathology perspective, these elaborations have noted that children are not passive recipients of socialization, but rather shape and reinterpret it. Each individual, therefore, experiences culture differently, as both interpretation and interaction are dynamic concepts. Previous to such elaborations, culture or ethnicity was traditionally identified and defined on the basis of phenotypic characteristics such as skin color. Some have argued that these groupings serve more as proxies of socioeconomic status (SES) than as meaningful cultural designations, asserting that lumping families and individuals under major demographic categories does not reflect culture, and may instead serve to mask rather than illuminate cultural differences (Abney, 1996; Fontes, 2001; Korbin, 1981, 1997, 2002).

In maltreatment research, culture has typically been treated as an independent variable to explain differences in incidence or prevalence of maltreatment; however, it has not often been partitioned from SES (Korbin, Coulton, Chard, Platt-Houston, & Su, 1998). Distinguishing between SES and culture is a complex problem that is difficult to resolve. Recent statistics regarding societal neglect report that after a decade of decline, the rate of children living in low-income families is on the rise, a trend that began in 2000. Today, 1 in 6 children live below the poverty line (Children's Defense Fund, 2004). Although the largest group of children in low-income families is White, Black and Latino children are significantly more likely to live in families with low incomes, and these minority groups largely account for the increase in low-income children (National Center for Children in Poverty, 2004). Thus, although it is important to distinguish poverty from culture when conducting cultural research, it seems that for some cultural groups, the presence of poverty is so pervasive that it becomes difficult to consider one in isolation from the other.

Among minority groups, there is disproportionate representation of child maltreatment reports (Holton, 1992); however, nothing in regard to cultural practices among minorities has been identified as contributing to child abuse and neglect (National Resource Council, 1993). As a consequence of reported rate differences, many studies have searched for cultural practices that are presumed to cause these rates, yet among them are few systematic investigations linking culture to maltreatment (for exceptions, see, e.g., Coohey, 2001; Dubanoski, 1981; Dubanoski & Snyder, 1980). NIS data have not reported any significant relationships between race, culture or ethnicity and the incidence of child maltreatment in any of their national investigations (USDHHS, 1981, 1988; Sedlack & Broadhurst, 1996).

In keeping with an ecological transactional view, an investigation of cultural influences on development should look to assess the vulnerability and protective factors associated with the culture of interest, such that cultural vulnerability factors would increase the risk for the occurrence of maltreatment, whereas protective factors might contribute to resilient functioning. For example, a study investigating the relationship between neighborhood structural factors and child maltreatment in African American and European American neighborhoods (Korbin et al., 1998) found that although there was a relationship between poverty and rates of reported child maltreatment, the strength of the relationship was weaker in predominantly African American neighborhoods as compared to predominantly European American neighborhoods. The relation-

ship between poverty and maltreatment was experienced differently between the two neighborhoods, each of which was characterized by different cultural values. The results of this investigation suggest that the African American neighborhoods had a stronger social cohesiveness that reduced the risk for the incidence of child maltreatment for individuals living in those neighborhoods. This is consistent with other research finding strong kinship and friendship links in African American communities (e.g., Stack, 1974).

However, in considering the developmental sequelae of maltreatment, several studies suggest that minority children who have been abused are at increased risk for maladaptation (Cohen, Deblinger, Mannarino, & Arellana, 2001). For example, sexually abused African American and Latino children have demonstrated higher rates of behavioral problems, depressive symptoms, and emotional trauma in comparison to demographically matched European American children (Morrow & Sorrell, 1989; Russell, 1986; Sanders-Phillips, Moisan, Wadlington, Morgan, & English, 1995). Unfortunately, there is a paucity of research investigating specific vulnerability and protective factors within cultures in the United States. To date, only one investigation of maltreated children has evaluated specific predictors of functioning within a minority culture (Flores, Cicchetti, & Rogosch, 2005; see section on resilience for further discussion).

EXOSYSTEM

The exosystem represents the social structures that form the immediate context in which families and individuals function. These structures include systems such as neighborhoods and the interconnections among its elements, such as school, peer group, church, and workplace (Bronfenbrenner, 1977), as well as informal social networks and formal support groups. The exosystem additionally refers to the availability of services, the availability of employment, and the socioeconomic climate (Cicchetti & Lynch, 1995).

Poverty is among the most salient aspects of the exosystem that has been associated with child maltreatment (Ards, Chung, & Meyers, 1998; Berger, 2004; Brown, Cohen, Johnson, & Salzinger, 1998; Gil, 1970; Lindsey, 1994; Waldfogel, 1998). It has long been recognized that poverty conditions may put families at risk for maltreatment as it causes increased stress for the family (Edelman, 1987; Huston, 1991; McLoyd & Wilson, 1991; Waldfogel, 2000), and as such, it may be an indirect precipitating factor in the occurrence of maltreatment. Whether the relationship between poverty and maltreatment operates

through direct or indirect mechanisms, it is clear that there is a strong co-occurrence of poverty and violence (J. L. Aber, 1994), and a number of studies have reported that low SES is a risk factor for violent behavior against children (Gelles & Straus, 1988; Straus & Kaufman-Kantor, 1986; Wolfner & Gelles, 1993).

Illustrating how factors from the exosystem and microsystem interact with each other, studies have focused on the independent additive and interactive effects of low SES and maltreatment on children's development (J. L. Aber, Allen, Carlson, & Cicchetti, 1989; Kaufman & Cicchetti, 1989; Okun, Parker, & Levendosky, 1994; Trickett, Aber, Carlson, & Cicchetti, 1991; Vondra, Barnett, & Cicchetti, 1989) by looking at the relation between poverty and specific family or parenting characteristics. For example, an investigation conducted with a population of urban African American young adults found that lower family income and younger caregiver age were related to reports of caregiver's high use of negative strategies (Koenig, Ialongo, Wagner, Poduska, & Kellam, 2002). These results suggest that the youngest and poorest caregivers use negative parenting strategies more frequently. Additionally, indicators of poverty such as perceived material hardship and infrequent employment, combined with parenting characteristics such as low parental warmth and use of physical discipline have been found to be predictive of child neglect (Slack, Holl, McDaniel, Yoo, & Bolger, 2004).

Specifically regarding unemployment, periods of high unemployment have been found to correlate with increases in the incidence of child abuse (Steinberg, Catalano, & Dooley, 1981). A number of studies have reported a link between unemployment and child maltreatment (Gelles & Hargreaves, 1981; Gil, 1970; Whipple & Webster-Stratton, 1991; Wolfner & Gelles, 1993). As with poverty, unemployment can be conceptualized as an exosystem factor that causes family stress and, perhaps through an indirect relationship, increases the likelihood for child maltreatment.

In the context of particular neighborhoods, the experience of community violence is another factor that has received particular attention with regard to its relation to child maltreatment (Cicchetti & Lynch, 1993, 1995; Lynch & Cicchetti, 1998; Martinez & Richters, 1993; Richters & Martinez, 1993), as high rates of community violence create stressful environments for family and individual functioning. For example, Lynch and Cicchetti conducted a 1-year longitudinal study of 7- to 12-year-old children to examine the mutual relationships among community violence, child maltreatment, and children's functioning over time. Rates of child maltreatment, particularly physical abuse, were related to levels of child-reported violence in

the community. Community violence was also related to the rate of physical abuse and the severity of neglect. Together, child maltreatment and exposure to community violence were related to different aspects of children's functioning; specific effects were observed for neglect and sexual abuse and for witnessing and being victimized by violence in the community. Exposure to community violence was related to children's functioning over and above the effects of more proximal contextual features (maltreatment). Consistent with an ecological-transactional perspective, there was evidence that children and their contexts mutually influence each other over time. Even after controlling for the effects of maltreatment status and prior effects of exposure to community violence, children's externalizing behaviors at Time 1 significantly predicted increased victimization by and witnessing of violence in the community at Time 2. Thus, this investigation established a clear relationship between community violence and child maltreatment and, moreover, provided empirical support for the ecological-transactional model of development.

Finally, social isolation and perceived lack of social support are additional aspects of the exosystem that have been associated with child maltreatment (Crouch, Milner, & Thomsen, 2001; Egeland, Bosquet, & Chung, 2002; Runtz & Schallow, 1997). Early studies by Garbarino and colleagues (Garbarino & Crouter, 1978; Garbarino & Sherman, 1980) have revealed that child abuse rates are higher in neighborhoods with fewer social resources in comparison to equally socioeconomically disadvantaged neighborhoods where resources are more plentiful. This link between child maltreatment and limited access to social and economic resources has also been associated with neglecting families (Dubowitz, 1999). Moreover, in high-abuse neighborhoods, parents often do not use the resources that are available to them for preventive services or interventions, such that social isolation from neighborhood networks, support groups, and extended family is commonly associated with maltreatment (Garbarino, 1977, 1982; Hunter & Kilstrom, 1979; Kempe, 1973). Child rearing can be influenced by information from educational resources, media, and social networks (Belsky, 1984; Garbarino & Gilliam, 1980; Sigel, 1986); however, maltreating parents who are isolated may not be exposed to the information that can improve their child-rearing beliefs and practices (Trickett & Sussman, 1988). Thus, social isolation among maltreating families leaves these families without support or resources that could improve their parenting practices and may contribute to the perpetuation of maltreatment (Berger, 2004; Dubowitz, 1999).

MICROSYSTEM

Broadly defined, the microsystem consists of any environmental setting that contains the developing person, including the home, the school, and the workplace (Bronfenbrenner, 1977). According to Belsky (1980), however, the microsystem is more narrowly represented as the family environment and, by extension, includes family dynamics as well as the parents' developmental histories, psychological resources, and child-rearing styles. With regard to child maltreatment, the microsystem can be conceptualized as the immediate environment or context in which the maltreatment occurs. The microsystem of maltreated children is characterized by stressful, chaotic, and uncontrollable events (Cicchetti & Lynch, 1993; P. W. Howes & Cicchetti, 1993; P. W. Howes, Cicchetti, Toth, & Rogosch, 2000), largely resulting from the most salient aspect of this system: the experience of maltreatment itself. Thus, the features of the maltreatment experience, such as type, severity, chronicity, and timing of maltreatment, are all characteristics of the maltreating microsystem (Cicchetti & Barnett, 1991b). Moreover, these features can have significant independent and interactive effects on child development (Manly et al., 1994, 2001) and have been associated with increased risk for specific developmental outcomes. For example, using hierarchical regression analysis, Manly and colleagues (2001) analyzed the contributions of developmental timing, maltreatment subtype, and maltreatment severity on a wide range of measures used to assess children's adjustment. The results highlighted the role of severity of emotional maltreatment in the infancy-toddlerhood period and physical abuse during the preschool period in predicting externalizing behavior and aggression; severity of physical neglect, particularly during the preschool period, was associated with internalizing symptomatology and withdrawn behavior. Chronic maltreatment, especially with onset in infancy-toddlerhood or the preschool period, was linked with more maladaptive outcomes.

Intergenerational Transmission of Child Maltreatment

In considering what might contribute to the onset of a maltreating family environment, considerable attention has been paid to parents' developmental histories. Among normative samples, there is ample evidence supporting the intergenerational transmission of parenting styles (Jacobvitz, Morgan, Kretchmar, & Morgan, 1991; van Ijzendoorn, 1992). Research regarding the intergenerational transmission of maltreatment has consistently supported the notion

that individuals with a history of maltreatment are more likely to maltreat their own children (Buchanan, 1996; Cicchetti & Aber, 1980; Conger, Burgess, & Barrett, 1979; Cooley & Braun, 1997; Egeland, 1988; Egeland, Jacobvitz, & Papatola, 1987; Egeland et al., 2002; Hunter & Kilstrom, 1979; Kaufman & Zigler, 1989; Widom, 1989). Offering theoretical explanations for these findings, some have asserted that the intergenerational transmission of abusive parenting behaviors may be a product of socialization and social learning (Feshbach, 1978; Herzberger, 1983). Others, however, argue that transmission occurs through the development of maladaptive representational models, which parents develop from their own early caregiving experiences. These experiences are then internalized and integrated into their self structures, organizing their subsequent parenting behaviors (Bowlby, 1980; Sroufe & Flee-son, 1986). Alternatively, Farrington, Lolliffe, Loeber, Stouthamer-Loeber, and Kalb (2001) suggest several additional pathways to the intergenerational transmission of violence, including the influence of genetics on temperament and personality.

Although empirical evidence is consistent in supporting the risk of continuity of maltreatment among those who endured childhood abuse experience themselves, there is a wide range of reported rates of its occurrence. For example, one prospective study that followed infants from birth through age 5 reported that 7.4% of parents with an abuse history maltreated their children (K. D. Browne & Herbert, 1997). In contrast, a retrospective study of the transmission of child sexual abuse reported that 33% of sexually abusive men and 50% of sexually abusive women experienced childhood sexual abuse (Collin-Vezina & Cyr, 2003). This discrepancy in reported rates has been associated with several methodological problems, including variation among studies in sample size, criteria for inclusion, and length of follow-up and whether a prospective or retrospective design was utilized (Egeland et al., 2002; Pears & Capaldi, 2002). Reliance on retrospective report in particular can often lead to overestimation (e.g., Hunter & Kilstrom, 1979). Therefore, it is difficult to estimate the rate of intergenerational transmission of maltreatment, especially when considering the complex interaction of risk, protective, and mediating factors that contribute to its emergence (Dixon, Browne, & Hamilton-Giachritsis, 2005; Egeland, 1988).

Several studies have focused on elucidating the mechanisms through which maltreatment is transmitted from one generation to the next by identifying specific protective and vulnerability factors (Bugental & Happaney, 2004;

Collin-Vezina & Cyr, 2003; Dixon, Browne, et al., 2005; Dunn et al., 2002; Leifer, Kilbane, & Kalick, 2004). For example, in a prospective investigation of families with newborns where at least one of the parents was physically and/or sexually abused as a child, 6.7% committed maltreatment by the time their child was 13 months old, in comparison to .4% of comparison families (Dixon, Browne, et al., 2005). Additionally, the presence of three significant risk factors provided partial mediation for the intergenerational transmission of child maltreatment: becoming a parent before age 21, residing with a violent adult, and having a history of mental illness and/or depression. This is consistent with other investigations that have suggested that poor maternal psychosocial functioning may promote escalation of risk across generations (Bifulco et al., 2002; Leifer et al., 2004).

In an extension of their investigation, Dixon, Browne, and colleagues (2005) found that the presence of poor parenting styles also mediated the intergenerational cycle of child maltreatment, although to a lesser degree than risk factors previously identified. Specifically, parents who had maltreatment histories had more negative attributions and unrealistic perceptions of their children and engaged their children in less positive interactions than parents who had not been maltreated as children. The presence of these poor parenting characteristics, when considered together with being a parent before the age of 21, having a history of mental illness, and/or living with a violent adult, provided a full mediation of the intergenerational cycle of maltreatment (Dixon, Hamilton-Giachritsis, & Browne, 2005).

In addition to research that has investigated the intergenerational transmission of maltreatment in a broad sense, a number of studies have focused specifically on the perpetuation of child sexual abuse. For example, one prospective study of sexually abused males revealed that particular experiences and patterns of childhood behavior are associated with victims becoming abusers later in life (Salter et al., 2003). Risk factors during childhood that predicted later offending included maternal neglect, lack of supervision, sexual abuse by a female, and frequent witnessing of serious intrafamilial violence. Additional investigations of the intergenerational transmission of child sexual abuse have identified severity of abuse, insecure attachment relationships with parental figures, and dissociative symptomatology following abuse as important distinguishing factors between those who break the cycle of abuse and those who perpetuate it (Collin-Vezina & Cyr, 2003). Together, these studies highlight the impact of risk factors occurring within multiple levels of the ecology in

contributing to the risk for the intergenerational transmission of child maltreatment.

Consistent with the principle of multifinality (Cicchetti & Rogosch, 1996), not all children who are maltreated go on to become abusive parents. Attempting to understand the mechanisms by which the cycle of maltreatment may be broken, a number of prospective studies have noted protective factors among parents who were maltreated but do not maltreat their own children (Collins-Vezina & Cyr, 2003; Egeland, Jacobvitz, & Sroufe, 1988; Hunter & Kilstrom, 1979); these factors include current social support, particularly from a supportive spouse, the past experience of a positive relationship with an adult during childhood, having undergone therapy either during adolescence or adulthood, and the absence of dissociative symptomatology following a prior experience of abuse. In relation to the therapy experience, those who can reflect on their own experiences of abuse with appropriate anger and who can direct responsibility for its occurrence to the perpetrator, rather than to the self, are less likely to maltreat their own children.

According to Cicchetti and Lynch (1993), in the ecological-transactional model, the balance among risk and protective factors in one's environment determines the likelihood of maltreatment's occurrence and influences the course of subsequent adaptation or maladaptation. Therefore, the presence of enduring protective factors and transient buffers may promote adaptation, such as the ability to break the cycle of abuse. Relatedly, the presence of enduring vulnerability factors and transient challengers increases the potential of conditions that support maltreatment. Thus, potentiating factors that are present at more proximal levels of the ecology (such as the microsystem) might help explain the mechanisms through which maltreatment is transmitted from one generation to the next. Additionally, an imbalance between protective and vulnerability factors where potentiating processes are heavily favored in the midst of few positive buffers may provide an account for the development of new maltreatment behaviors in individuals who were not themselves maltreated.

Personal Resources of Maltreating Parents

The resources of parents in maltreating families also contribute to the construction of the microsystem. A number of studies have identified areas of functioning, both psychological and biological, in which maltreating parents have demonstrated deficits (see Azar, 2002, for review). For example, parents who become abusive have been described as less psychologically complex and personally in-

tegrated than parents who do not maltreat their children (Brunquell, Crichton, & Egeland, 1981). Parental psychopathology has been associated with an increased risk for maltreatment, specifically in regard to depression (Burke, 2003; Lahey, Conger, Atkeson, & Treiber, 1984; Sloan & Meier, 1983) and parental drug use (Ondersma, 2002; Windham et al., 2004; Wolfner & Gelles, 1993). Thus, the interaction of parental psychopathology with the experience of maltreatment poses a serious threat to normal child development (Walker, Downey, & Bergman, 1989).

Additionally, the ability to cope with stress has been well researched in relation to the risk for child maltreatment. Several studies have noted that maltreating parents lack impulse control, especially when aroused or stressed (Altemeier, O'Connor, Vietze, Sandler, & Sherrod, 1982; Brunquell et al., 1981), and suggest that perhaps they are biologically predisposed to overreact to stressful stimuli (McCanne & Milner, 1991; Milner, 2000). In light of the various macrosystem and exosystem challenges that face maltreating families, each of which contribute to the experience of stress, the failure to cope with stressful life events (Crittenden, 1985; Wolfe, 1985) does not bode well for maltreating individuals' ability to successfully handle the challenges associated with parenting (Cicchetti & Lynch, 1995).

FAMILY DYNAMICS/SYSTEMS

Maltreating families are commonly characterized by maladaptive and disruptive relationships. Moreover, anger and conflict are pervasive features of maltreating families (Trickett & Sussman, 1988), within which violent parents are likely to attack multiple family members. Several studies have supported the association between exposure to domestic violence and child maltreatment (Duncan, 1999; Edelson, 1999; Perry, Hodges, & Egan, 2001; Windham et al., 2004). Evidence regarding interparental aggression suggests that witnessing such conflict affects children's developing beliefs about close relationships and as such may contribute to later problems in social and emotional functioning (Grych, Wachsmuth-Schlaefel, & Klockow, 2002).

Whereas interpersonal conflict may be more characteristic of abusive families, social isolation may be more characteristic of neglecting families (Crittenden, 1985), limiting children's exposure to fewer nonparental models of emotional communication (Salzinger, Feldman, Hammer, & Rosario, 1993). In general, however, husbands and wives in maltreating families are less warm and supportive, less satisfied in their conjugal relationships, and more aggressive

and violent than spousal partners in nonabusive families (P. W. Howes & Cicchetti, 1993; Margolin, 1998; A. Rosenbaum & O'Leary, 1981; Rosenberg, 1987; Straus, Gelles, & Steinmetz, 1980; Straus & Kaufman-Kantor, 1986).

A distinctive feature that has been noted in maltreating families is the chaotic and unstable nature of the family system, often characterized by a shifting constellation of adult and child figures moving into and out of the home (Polansky, Gaudin, & Kilpatrick, 1992). Recently, the application of a systems approach to understanding family interactions in maltreating families has received particular attention, as Davies and Cicchetti (2004) urge researchers toward better integration of developmental psychopathology and family systems constructs in guiding future research. Family systems theory (Minuchin, 1985) emphasizes the reciprocal relationships between various subsystems within the family (family dyads, triads, etc.). The principal goal in family systems research is to achieve a comprehensive rendering of the interplay among relationships and individuals in the whole family unit, with a specific focus on identifying relationship structures, interpersonal boundaries, power distributions, and communication patterns (Cox & Paley, 1997; Minuchin, 1985).

Most family systems research to date has focused on family conflict and marital conflict in relation to punishment of children and the development of aggression, and has not been conducted specifically with maltreating families. They are mentioned here, however, because understanding the emergence of patterns of physical conflict may provide information regarding the escalation of this conflict into child maltreatment. For example, one prospective study suggests that marital conflict and parental individual hostility has been associated with an increased risk for more frequent and severe physical punishment of children at ages 2 and 5 (Kanoy, Ulku-Steiner, Cox, & Burchinal, 2003). Additional work has linked parental physical aggression between partners (or in dyads where one is the aggressor and one is victim) to increased direct physical aggression toward their children (Mahoney, Donnelly, Boxer, & Lewis, 2003). Marital aggression was linked to externalizing problems among parents and children and also to children's internalizing problems. This provides support for the notion that individual parent and child characteristics as well as marital qualities must be examined in the context of the whole family over time to gain an understanding of the emergence of physical punishment patterns.

With respect to maltreating families, P. W. Howes et al. (2000) coded aspects of affective, organizational, and relational features in maltreating and nonmaltreating family units. Through this family systems analysis, some maltreat-

ing families could be reliably identified on the basis of systemic differences. Specifically, sexually abusive families had more difficulty regulating anger, evidenced more chaos and less role clarity, and relied less on adaptive-flexible relationship strategies than nonmaltreating families. Thus, P. W. Howes and colleagues posit that a pattern of disorganized roles and chaotic interactions, in combination with affect dysregulation and rigid relationship skills, are discriminating characteristics of sexually abusive family systems. This study highlights that a disorganized family structure may be as detrimental to children as the specific forms of abuse they suffer. The importance of family climate and structure, above and beyond individual maltreatment acts, has vast implications for the development of intervention and prevention policies, underscoring the need for interventions at the family level beyond those that are targeted solely at children (for further discussion, see later section on intervention and prevention).

Parenting Styles

Considering ecological proximity to the child, the actual parenting styles and attitudes that maltreating parents contribute to the family microsystem may have the most direct impact on their children's ontogenic development (Cicchetti & Lynch, 1993). In general, studies of parent-child interactions among maltreating families have revealed maladaptive and differential behaviors in maltreating families in comparison to nonmaltreating families. Maltreating parents are less satisfied with their children, perceive child rearing as more difficult and less enjoyable, use more controlling disciplinary techniques, do not encourage the development of autonomy in their children, and promote an isolated lifestyle for themselves and their children (Azar, 2002; Rogosch, Cicchetti, Shields, & Toth, 1995; Trickett et al., 1991; Trickett & Kuczynski, 1986; Trickett & Sussman, 1988). Specifically, abusive parents tend to show fewer physical and verbal behaviors to direct their children's attention (Alessandri, 1992; Bousha & Twentyman, 1984), have more unrealistic expectations of their child (Putallaz, Costanzo, Grimes, & Sherman, 1998), and attribute more negative intentions to their child's behavior in comparison to nonmaltreating parents (Dixon, Hamilton-Giachritsis, et al., 2005; Zeanah & Zeanah, 1989).

Abusive parents also show less positive affect and a low degree of reciprocity during dyadic interactions (Burgess & Conger, 1978; Lahey et al., 1984) and are less supportive, playful and responsive to their children (Burgess & Conger, 1978; Egeland, Breitenbucher, & Rosenberg, 1980; Kavanaugh, Youngblade, Reid, & Fagot, 1988; Reid,

Kavanaugh, & Baldwin, 1987; Trickett & Sussman, 1988; Twentyman & Plotkin, 1982). Even with infants, abusive mothers have been described as more controlling, interfering, and hostile (Crittenden, 1981, 1985). Moreover, abusive mothers consistently show higher rates of aversive behavior directed toward their children than do nonabusive mothers (Cerezo, 1997), with average rates as much as twice the rate of aversive behavior displayed by nonmaltreating mothers (Cerezo & D'Ocon, 1995). This is significant in light of the evidence that aversive behavior is more likely to be reciprocated, escalating into negative exchanges of longer duration than in nonabusive families (Loeber, Felton, & Reid, 1984). Regarding neglecting families, neglecting mothers tend to hold few expectations for their children, may be inconsistent in their response to them, and lack the ability to follow through with age-appropriate limits when upset (Crittenden, 1988).

Serious distortions in the parent-child relationship have often been noted in maltreating families, such that children are faced with the inappropriate expectation that the child should act as a caretaker for the parent (P. W. Howes & Cicchetti, 1993). Thus, children act as though they have traded roles with their caregiver (Dean, Malik, Richards, & Stringer, 1986), as the child appears to be the more nurturing and sensitive member of the dyad. Further support for the "parentification" phenomenon has been demonstrated through the analysis of narratives of maltreated preschoolers (Macfie et al., 1999). In this investigation, children completed story stems that introduced stressful family situations. Results indicated that maltreated children portrayed parents and children as responding to distress less often. Maltreated children portrayed themselves stepping into the story more often to relieve children's distress than did nonmaltreated preschoolers, thereby taking on the nurturing role. It seems that such role reversal may be indicative of a developing internal working model to give care rather than to receive it. (See later section on internal working models for further discussion of narrative representation among maltreated children.)

Finally, significant differences have emerged in terms of disciplinary practices of maltreating parents. Maltreating parents have been described as less verbal in approaching conflict resolution (Silber, 1990) and less successful at handling discipline confrontation (Rogosch, Cicchetti, Shields, et al., 1995). With regard to perceptual differences, abusive parents are more likely to view their children as aggressive, intentionally disobedient, and annoying, even when other observers fail to detect such differences (Dixon, Hamilton-Giachritsis, et al., 2005; Mash, John-

ston, & Kovitz, 1983; Reid et al., 1987). Thus, differences in maltreating parents' perceptions and expectations of their children may contribute to the adoption of inappropriate disciplinary practices (Milner & Chilamkurti, 1991). For example, maltreating parents are more likely to use punishment, threats, coercion, and power assertion and less likely to use reasoning and affection in disciplining and controlling their children (Chilamkurti & Milner, 1993; Loeber et al., 1984; Oldershaw, Walters, & Hall, 1986; Trickett & Sussman, 1988). Furthermore, the disciplinary action chosen is less likely to be contingent on the type of behavior displayed by the child and may be age-inappropriate (Crittenden, 1981; Trickett & Kuczynski, 1986). Additionally, abusive parents are more intrusive, more inconsistent, and less flexible in their attempts to gain compliance from their children (Oldershaw et al., 1986), all of which are negatively associated with the development of internalization of parental ideals (Grusec & Goodnow, 1994). Thus, the negative discipline practices of maltreating parents may contribute to a cycle of escalating harsh parenting as children fail to internalize their parents' values and continue to behave in opposition to their parents' maladaptive expectations.

Some contend that rather than specific parental values, whole relationships are internalized and perpetuated by the individual, such that relationship history can influence children's attitudes, affects, and cognitions, organizing the self and shaping individual development (Sroufe & Flee-son, 1988). As a whole, maltreating families do not successfully resolve the salient issues of family development (Cicchetti & Howes, 1991); instead, maltreating parents do little to foster the success of their children as they face each stage-salient developmental challenge (cf. Cicchetti, 1989, 1990). Thus, maltreated children may be at a disadvantage to face subsequent challenges as the negative potentiating factors, which pervade their microsystem, may be internalized and carried throughout the life span.

PSYCHOLOGICAL ONTOGENIC DEVELOPMENT

The failure of the average expectable environment that is represented by child maltreatment culminates in its effects on children's ontogenic development. At the level of psychological ontogenic development, the negotiation of central tasks of each developmental period organizes one's developmental trajectory toward subsequent competence or

incompetence (Cicchetti, 1989; Cicchetti & Lynch, 1995). An ecological-transactional perspective views child development as a progressive sequence of age- and stage-appropriate tasks in which successful resolution of tasks at each developmental level must be coordinated and integrated with the environment, as well as with subsequently emerging issues across the life span (Cicchetti & Lynch, 1993). These tasks include the development of emotion regulation, the formation of attachment relationships, the development of an autonomous self, symbolic development, moral development, the formation of peer relationships, adaptation to school, and personality organization. Thus, stage-salient tasks are hierarchically organized as each new task builds on and is influenced by the resolution of previous developmental tasks. Poor resolution of stage-salient issues may contribute to maladaptation over time as prior history influences the selection, engagement, and interpretation of subsequent experience; however, the current context is in constant transaction with environmental supports (Sroufe, Carlson, Levy, & Egeland, 1999). Thus, ontogenic development is a lifelong dynamic task, and consistent with Gottlieb's (1991, 1992) notions of probabilistic epigenesis, individuals are continually affected by new biological and psychological experiences, leaving developmental pathways susceptible to modification throughout the life span (Cicchetti & Lynch, 1995).

Emotion Regulation

Emotion regulation, conceptualized as the ability to modulate one's emotional arousal such that an optimal level of engagement with the environment is fostered, is a developmentally acquired process that emerges from increasing differentiation and hierarchical integration of biological and psychological systems (Cicchetti, 1993; Cicchetti, Ganiban, & Barnett, 1991; Cicchetti & Sroufe, 1978; Shields & Cicchetti, 1997). Emotion regulation evolves as a function of both intrinsic features and extrinsic socio-emotional experiences within the context of early parent-child interactions (A. Maughan & Cicchetti, 2002; Thompson, 1990, 1994). At the biological level, important intraorganismic factors for the development of emotion regulation include organizational changes in central nervous system functioning, cerebral hemispheric lateralization, and the development of neurotransmitter systems (Cicchetti et al., 1991; Davidson, 1984; N. A. Fox & Davidson, 1984; Kelley & Stinus, 1984; Sperry, 1982; Tucker, 1981). Extraorganismically, children's emotional experiences, expressiveness, and arousal are influenced by care-

givers' response to and tolerance of affect. Parents' socialization of affective displays during early interpersonal exchanges serve as the model through which aspects of emotional regulation may be learned (Hesse & Cicchetti, 1982; Stern, 1985; Thompson, 1990).

Given the severe disturbances in the average expected environment provided by maltreating families, considerable evidence has mounted to demonstrate the detrimental effects of maltreatment on children's emotional development and regulation. Specifically, maltreated children have shown deviations in a number of processes that underlie the development of emotion regulation; these include emotion expression (e.g., Gaensbauer, 1982), recognition (e.g., Camras, Sacks-Alter, & Ribordy, 1996; Pollak, Cicchetti, Hornung, & Reed, 2000), understanding (e.g., Shipman, Zeman, Penza, & Champion, 2000), and communication (e.g., Beeghly & Cicchetti, 1994).

Emotion Expression

Divergence in maltreated children's emotional expression has been noted as early as 3 months of age, where severely physically abused infants have evinced increased rates of fearfulness, anger, and sadness during mother-infant interactions (Gaensbauer, Mrazek, & Harmon, 1981). The expression of fear and anger among physically abused infants at 3 months of age is a particularly salient finding considering that the normative ontogenic development of these affects does not typically occur until approximately 7 to 9 months of age (Sroufe, 1996). In contrast, neglected infants displayed an attenuated range of emotional expression and an increased duration of negative affect as compared to nonmaltreated infants (Gaensbauer et al., 1981).

To examine the affective input that maltreated children receive, Camras and colleagues (1988, 1990) conducted a series of investigations of maternal facial expressions. When asked to deliberately produce facial expressions, maltreating mothers' demonstrations of emotion faces were less easily identified by observers than were the expressions of nonmaltreating mothers (Camras et al., 1988). During mother-child interactions, maltreating mothers differed from nonmaltreating mothers with regard to the expression of sadness (Camras et al., 1990). Taken together, the emotion displays of abused and neglected infants highlights the centrality of interactions with caregivers in shaping the development of affect expression or differentiation. Moreover, maternal emotional expression ability contributes to their children's ability to recognize facial emotion (Camras et al., 1988). Thus, maltreated children are

already at risk for differential emotion regulation developmental trajectories within the first 3 months of life.

Emotional Recognition

The ability to identify basic emotions from both facial and contextual cues is normatively mastered by the preschool years (Reichenbach & Masters, 1983; Walden & Field, 1982). Maltreated children, however, have demonstrated less accurate recognition of emotions than nonmaltreating children, above and beyond the effects of cognitive ability (Camras, Grow, & Ribordy, 1983; Camras et al., 1988; During & McMahon, 1991). Further investigation by Camras and colleagues (1990), however, has revealed that despite overall deficits in emotion recognition performance, analysis of maltreated children's processing errors suggested that maltreated children have a selective bias, or hypersensitivity, toward the detection of anger.

Developmentally, early limitations on the capacity for information processing require children to focus their attention on only the most salient aspects of the environment (Bjorklund, 1997); thus, children's emotional development is contingent on what is experienced. For physically abused children, displays of anger may be the greatest predictor of threat, often experienced as the most salient aspect of the environment. As such, Pollak et al. (2000) hypothesized that physically abused preschool children would demonstrate an increased sensitivity to anger-related cues perhaps also resulting in decreased attention to other emotional cues. The results of their study revealed that when physically abused children were exposed to a perceptual scaling task, they perceived angry faces as highly salient and more distinctive relative to other emotion categories (Pollak et al., 2000). Additionally, when asked to match facial expressions to an emotional situation, physically abused children showed a response bias for anger such that when they were uncertain which facial expression to choose, they showed a lower threshold for selecting anger. Moreover, physically abused children have displayed more broad perceptual category boundaries for perceiving anger than nonmaltreated children (Pollak & Kistler, 2002) and have required less visual information to detect the presence of angry facial expressions (Pollak & Sinha, 2002).

Consistent with behavioral findings, psychophysiological studies using event-related potentials (ERPs) have also provided support for the notion that physically abused children allocate more processing resources when attending to anger, but respond similarly to nonmaltreated children when attending to happy and fearful faces (Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Pollak, Klorman,

Thatcher, & Cicchetti, 2001; Pollak & Tolley-Schell, 2003; see later section on cognitive brain event-related potentials). Thus, it seems that physically abused children do not have emotion recognition or affective information-processing deficits in a global sense; rather, differential processing of emotion appears to be specific to anger. It is certainly conceivable that an increased sensitivity to anger might be adaptive for physically abused children, as it would allow for hypervigilant detection of potential threats, but successful regulation includes the capacity for flexibility and control over attention. Pollak and Tolley-Schell posit that early experiences of abuse may alter the development of perceptual systems by decreasing the minimum amount of threat-related stimulation needed to engage focused attention on the threat-inducing stimuli; if physically abused children respond more quickly and/or strongly to signals of threat, then problems disengaging attention away from anger may emerge. Using a selective attention paradigm with an affective component, both physiological and behavioral measures were employed to assess children's orienting reaction and response time during valid trials, and children's disengagement reaction and response time during invalid trials (Pollak & Tolley-Schell, 2003). Psychophysiological data confirmed the hypothesis that physically abused children demonstrate a selective increase in ERP response (as measured by P3B) on invalid angry trials, providing evidence that increased attentional resources were required to disengage from previously cued angry faces only. Physically abused children also demonstrated faster reaction times in the valid angry condition, consistent with the notion that abused children orient rapidly to cues primed by anger. There were no differences, however, in physically abused children's psychophysiological responses or reaction times to happy trials, providing further support for a specific or differential deficit involving attentional processing of anger.

It is possible that the early expression of fear, anger, and sadness that emerges among physically abused infants within the first 3 months of life reflects deviations at the neural level, whereby fear-processing synapses are strengthened and/or positive affect-processing synapses are pruned, leading to later deviations in attentional control in response to anger-related cues. These emotion recognition and processing biases, which develop during the 1st year of life, could leave physically abused children vulnerable to unsuccessful resolution of stage-salient developmental tasks. For example, one possible pathway to maladaptation might include a predisposition for developing an atypical pattern of attachment, especially given

that the development of disorganized attachment has been linked to early experiences of fear (Cicchetti & Lynch, 1993). At subsequent developmental levels, physically abused children might also be predisposed to manifest social information-processing deficits and difficulties with peer relationships. Social information biases that are prevalent among maltreated children's peer interactions indicate that maltreated children are more, rather than less, likely to respond to angry or aggressive emotional cues (Dodge, Pettit, & Bates, 1990; Dodge et al., 1997; Rieder & Cicchetti, 1989); thus, later social biases are consistent with early attentional biases in response to expressions of anger.

Emotional Behavioral Reactivity

Further evidence supports the persistence of emotion dysregulation into the preschool and school-age years, as demonstrated by studies of maltreated children's emotional behavioral reactivity to exposure to interadult anger (Cummings, Hennessy, Rabideau, & Cicchetti, 1994; Hennessy, Rabideau, Cicchetti, & Cummings, 1994; A. Maughan & Cicchetti, 2002). Specifically, physically abused school-age children display more fear in response to videotaped angry adult interactions as compared to nonabused comparison children who are matched on exposure to interpersonal aggression (Hennessy et al., 1994). Physically abused boys in particular show more aggression as well as more coping responses (i.e., intervening in the angry exchange or comforting mother) during exposure to live simulations of interadult anger (Cummings et al., 1994). Extending these findings, A. Maughan and Cicchetti applied a person-oriented approach to assess how different maltreatment experiences (physical abuse and neglect), in conjunction with a history of exposure to interadult violence, may impact children's emotion regulation abilities in response to live simulations of interadult anger directed toward their mother. Results indicated that maltreatment alone predicted children's complex patterns of emotion; neither interadult violence nor its interaction with maltreatment accounted for children's emotional response patterns to the interadult anger. Moreover, approximately 80% of the maltreated children evidenced dysregulated emotion patterns (undercontrolled/ambivalent or overcontrolled/unresponsive), in comparison to only 36% of the nonmaltreated children (A. Maughan & Cicchetti, 2002). Notably, the emotional response patterns of maltreated children provide support for Davies and Cummings's (1994) emotional security hypothesis that emotional security is largely determined by familial relations in the early care-

giving environment. With regard to maltreated children, unpredictable and threatening interpersonal exchanges that occur during direct and indirect interactions with the caregiver often characterize their early environment, resulting in children's increased emotional insecurity. Without adequate emotional security, a child's self-regulatory abilities may be easily overwhelmed by environmental stressors, leading to the development of over- and underregulation (Cole, Michel, & Teti, 1994), as exemplified by the high rate of emotional dysregulation patterns found among maltreated children (A. Maughan & Cicchetti, 2002).

Maladaptive emotion regulation has additionally been observed among maltreated children during peer interactions. To investigate emotion regulation abilities among school-age children, Shields and Cicchetti (1997) developed an emotion regulation Q-sort to address the lack of available methods for the assessment of observed emotion regulation beyond early childhood. Both demonstrating convergent and divergent validity, the Emotion Regulation Q-sort was able to distinguish between maltreated and non-maltreated children on the basis of whether their emotions were regulated or dysregulated. Through further applications of this methodology, Shields and Cicchetti (1998) demonstrated the relation of emotion dysregulation and attention to the development of reactive aggression among maltreated children. Specifically, maltreated children are more likely to show increased rates of aggression, as well as increased distractibility, overactivity, and poor concentration (characteristic of children with deficits in attention modulation). Furthermore, attention deficits mediated the effects of maltreatment on emotional lability/negativity, inappropriate affect, and attenuated emotion regulation. Therefore, it seems that attention processes (which may have their roots in early anger recognition biases that develop during infancy) may interact with negative representations and maladaptive social information processing to foster emotional negativity and reactivity among maltreated children; this in turn seems to provoke reactive aggression, particularly among children with histories of physical abuse.

Additionally, evidence supports that emotional dysregulation may mediate the increased risk of bullying and victimization that has been noted among maltreated children (Shields & Cicchetti, 2001), highlighting how the internalization of salient aspects of the early caregiving relationship may have maladaptive implications among these children. As maltreated children are victimized by parents, they may develop a working model of relationships as dangerous and malevolent that incorporates the roles of both

bully and victim. These cognitive-affective structures may then guide behaviors and peer interactions, promoting emotional constriction or atypical emotional responsiveness and coloring children's interpretations of the behavior of social partners.

FORMATION OF ATTACHMENT RELATIONSHIPS

The formation of attachment relationships represents a major stage-salient developmental task for toddlers, beginning approximately at the end of the 1st year of life. While overt patterns of attachment emerge around 12 months of age, parent-child interactions throughout the 1st year create the context for early affect regulation experiences, physiological regulation, and biobehavioral patterns of response, all of which become the foundation from which the capacity for attachment emerges (Gunnar & Nelson, 1994; Hofer, 1987; Pipp & Harmon, 1987; Spangler & Grossman, 1993). Infants rely on their early experiences with their caregivers to derive a sense of security, and they use this relationship as a base from which to explore the environment (Sroufe, 1979). Thus, it is essential for the caregiver to be sensitive, responsive, and reliable, so that the child may use these regularities to develop internal models and create expectations for the future. The absence of contingent responsiveness on the part of parents can impede infants' ability to develop feelings of security in their primary attachment relationship (Sroufe & Waters, 1977).

Ultimately, successful resolution of this developmental task is for the child to be able to enter into a goal-corrected partnership where the caregiver and the child share internal states and goals (Bowlby, 1969/1982; Cicchetti, Cummings, Greenberg, & Marvin, 1990). The child forms representational models of the self, other, and self in relation to the other through negotiations and interactions within the primary caregiving relationship (Bowlby, 1969/1982). The mental representational models that emerge from interactions in the first attachment relationship organize children's affects, cognitions, and expectations about future interactions, thereby influencing all subsequent relationships (Cicchetti & Lynch, 1993; A. Nash & Hay, 1993; Sroufe, 1989; Sroufe, Carlson, & Shulman, 1993).

Studies of attachment among maltreated children, using the classic Strange Situation paradigm (Ainsworth & Wittig, 1969), have consistently found that maltreated children are more likely than nonmaltreated children to form insecure attachments with their caregivers (Cicchetti & Bar-

nett, 1991a; Crittenden, 1985; Egeland & Sroufe, 1981; Lamb, Gaensbauer, Malkin, & Schultz, 1985; Schneider-Rosen, Braunwald, Carlson, & Cicchetti, 1985). Utilizing the traditional classification scheme for attachment relationships, in which children may be classified as Type A, anxious avoidant; Type B, securely attached; or Type C, anxious resistant (Ainsworth, Blehar, Waters, & Wall, 1978), these early studies found that two-thirds of maltreated children displayed insecure attachment (Types A or C), whereas the reverse pattern was true in nonmaltreated children (Schneider-Rosen et al., 1985; Youngblade & Belsky, 1989).

The attachment behaviors of maltreated children, however, were frequently described as difficult to fit within this original attachment classification schema (e.g., Egeland & Sroufe, 1981); instead, maltreated children showed inconsistent or disorganized strategies for dealing with separations and reunions with their caregivers. Consequently, the observation of the attachment behaviors of maltreated children led to the identification of an additional pattern of attachment, named disorganized attachment, or Type D, by Main and Solomon (1990). Because inconsistent care is a hallmark of maltreating families, it is quite likely that parenting that is insensitively overstimulating (associated with avoidant attachment) and insensitively understimulating (associated with resistant attachment) may pervade parent-infant interactions in maltreating families (Belsky, Rovine, & Taylor, 1984; Crittenden, 1985; Lyons-Ruth, Connell, Zoll, & Stahl, 1987). The combination of these two contradictory caregiving styles could lead to the inconsistent behaviors that characterize Type D attachment (Cicchetti & Lynch, 1995). Beyond disorganization, infants with Type D attachment also often display bizarre behaviors in the presence of their caregiver, such as interrupted movements and expressions, apprehension, dazing, freezing, and stilling behaviors (see also Fraiberg, 1982).

Relatedly, Crittenden (1988) identified yet another atypical pattern of attachment through observation of maltreated children. This pattern, which she labeled avoidant-resistant or Type A-C attachment, describes a pattern encompassing displays of moderate to high levels of both avoidant and resistant attachment behaviors. There are theoretical distinctions between Main and Solomon's (1990) Type D attachment and Crittenden's (1988, 1992) Type A-C attachment; however, most researchers have come to consider the Type A-C pattern as a subset of behaviors within the range of Type D attachment patterns (Cicchetti, Toth, & Lynch, 1995). Regardless, there is consensus in the field that both Type A-C and Type D attachments represent

atypical patterns of attachment that are distinct from secure and insecure patterns.

Apart from their association with maltreatment, atypical attachment patterns are also linked to having a caregiver with depression, substance abuse, or unresolved loss or trauma resulting from the parent's own childhood attachments (Ainsworth & Eichberg, 1991; Cicchetti et al., 1995; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991; Main & Hesse, 1990; Teti, Gelfand, Messinger, & Isabella, 1995). Thus, converging evidence supports the role of experience in the development of disorganized patterns of attachment, which is not unique to the experience of maltreatment per se, but may emerge from the context of severely disturbed parenting.

Using revised attachment schemes to include the classification of atypical attachment in addition to traditional secure and insecure patterns, there is a huge preponderance of atypical or insecure attachment among maltreated children (Barnett, Manly, & Cicchetti, 1999; Carlson, Cicchetti, Barnett, & Braunwald, 1989; Crittenden, 1988; Lyons-Ruth, Connell, & Zoll, 1989; Lyons-Ruth et al., 1987). Many studies report attachment insecurity for maltreated children to be 80% to 90%. Specific to Type D attachment, apart from Type A or C insecure patterns, studies have reported that up to 80% of maltreated infants display disorganized patterns of attachment compared to rates of approximately 20% of Type D attachment among demographically comparable, low SES, nonmaltreated children (Carlson et al., 1989). A meta-analysis of disorganized attachment in early childhood reports about 15% Type D attachment in normative middle-class families; in other social contexts, such as the case of child maltreatment, rates are far higher (van Ijzendoorn, Schuengel, & Bakermans-Kranenburg, 1999).

Substantial stability in insecure patterns has also been noted among maltreated children, whereas those that display initial secure attachments tend to become insecure over time (Cicchetti & Barnett, 1991b; Schneider-Rosen et al., 1985). The opposite pattern tends to be true for nonmaltreated children such that secure attachment is stable, and children who are insecurely attached are likely to develop secure attachment (Lamb, Thompson, Garnder, & Charnov, 1985). Providing further support for the stability of insecure attachment across 12, 18, and 24 months, Barnett, Ganiban, and Cicchetti (1999) found support for a strong association between child maltreatment in infancy and the development of Type D attachment. Specifically, 66.7% of children were classified as Type D at both 12 and 18 months, with maltreated infants significantly more likely than nonmaltreated infants to be classified as Type D

at both ages (56% versus 19% for maltreated and comparison infants, respectively). Moreover, this pattern persisted at least through the toddler years, such that 81.3% of children classified as Type D at 18 months received the same classification at 24 months (Barnett et al., 1999). These findings suggest that Type D attachment is not transitory, reinforcing the notion that early attachment relationships organize future behavior. Additionally, this study extended our knowledge regarding the development of Type D attachment through the inclusion of measures of child temperament such as negative expressivity. Analyses revealed that Type D attachment is not a function of children's negative expressivity, indicating discriminant validity for the construct, nor is negative expressivity related to maltreatment, thus lending support to the notion that infant difficulty does not predispose one to maltreatment. Also, as rates of parenting problems increased in severity, atypical patterns of attachment increased and secure attachment patterns decreased, highlighting the influence of parenting behaviors on Type D attachment. Finally, attachment disorganization predicted the degree and direction of child vocal distress change such that the securely attached children decreased in vocal distress as they matured, but the Type D attached children increased in vocal distress between 12 and 18 months, suggesting that attachment disorganization may disrupt the development of emotional regulatory systems (Barnett et al., 1999).

Further research on the relationship between emotion and disorganized attachment has identified frightened and frightening behavior associated with the caregiver as central to the development of disorganized attachment. Once fear becomes connected to the caregiver, the child may become unable to rely on the attachment figure as a source of security or safety (Lyons-Ruth, Bronfman, & Parsons, 1999; Main & Hesse, 1990). The experience and expression of fear, which emerges early among many maltreated children, may impair children's ability to regulate and organize their affect during activation of their attachment system (Cicchetti & Lynch, 1993). Additional support for a link between disorganized attachment and the development of emotion regulation problems has been provided through physiological evidence. For example, children with Type D attachments have been found to display indices of physiological stress, such as increased heart rate and salivary cortisol responses, to the Strange Situation; infants with secure attachments do not display such stress responses (Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Spangler & Grossman, 1993). Similar patterns of physiological dysregulation have been associated with infants placed into foster care (Dozier, Levine, Stovall, & Eldreth, 2001).

Considering that all children who enter foster care have experienced severe disruptions in their relationships with primary caregivers, and that many have experienced maltreatment prior to their entrance into the foster care system, atypical patterns of glucocorticoid production among these youngsters underscores the relationship between attachment insecurity and emotion regulation difficulties.

The stability of early atypical attachment among maltreated children places them at extreme disadvantage to achieve adaptive outcomes in other domains of self- and interpersonal development (Cicchetti & Lynch, 1993). Consistent with the transactional nature of development, early attachment does not cause later maladaptation in a linear function; rather, prior history influences the subsequent selection, engagement, and interpretation of experience. Thus, early insecurity in attachment can be conceptualized as an “initiator of pathways probabilistically associated with later pathology” (Sroufe et al., 1999, p. 1). Among the developmental sequelae associated with insecure attachment are the presence of externalizing and internalizing symptomatology (Lyons-Ruth & Easterbrooks, 1995), problematic stress management, elevated risk for externalizing problem behavior, and the tendency to develop dissociative behavior later in life (Ogawa, Sroufe, Weinfield, Carlson, & Egeland, 1997; van Ijzendoorn et al., 1999). Additionally, maltreated children’s representational models, which develop in the context of the attachment relationship, may moderate the effects of maltreatment on children’s perceived competence and depressive symptomatology (Toth & Cicchetti, 1996). Furthermore, evidence supports that insecure patterns of attachment will persist into adulthood, contributing to difficulties with family relationships (Bartholemew, 1990; Crittenden, 1988; Crittenden & Ainsworth, 1989; Feldman & Downey, 1994; P. W. Howes & Cicchetti, 1993; Main & Goldwyn, 1984). For example, in examining results of the Adult Attachment Interview among maltreating parents, Crittenden, Partridge, and Claussen (1991) reported rates of either both dismissing, both preoccupied-engaged, or one of each within the maltreating couple that exceeded 90%. This was in stark contrast to demographically matched nonmaltreating couples where secure attachments from both partners were more likely. Among maltreating couples, however, unions between two securely attached individuals or between one secure and one insecure individual were nearly nonexistent, providing evidence for assortative mating that may perpetuate the intergenerational transmission of insecure attachment patterns as well as child maltreatment. From an ecological-transactional perspective, the primary attachment relationship remains a salient developmental

issue across the life span, as it lays the foundation for representational models and subsequently shapes an individual’s selection, engagement, and interpretation of all future experiences, including the ability to successfully resolve ensuing developmental tasks.

DEVELOPMENT OF AN AUTONOMOUS SELF

The infant’s concept of self is believed to emerge from early parent-child interactions within the context of the primary caregiving relationship (Bowlby, 1988; Bretherton & Waters, 1985; Emde, 1983; Mahler, Pine, & Bergman, 1975; Sroufe, 1989; Stern, 1989). Secure attachment to mother is associated with a number of adaptive self processes, including, for example, more complex self-knowledge (Pipp, Easterbrooks, & Harmon, 1992). Similarly, maltreated children who are able to develop secure attachments with their mother are less likely to display the self-concept deficits that are common among insecurely attached maltreated children (Beeghly & Cicchetti, 1994; Schneider-Rosen & Cicchetti, 1984; Toth & Cicchetti, 1996).

As development proceeds into toddlerhood, the stage-salient task shifts to the development of autonomous functioning, as the responsibility of self-management and the regulation of affect moves away from the context of the caregiver-infant relationship onto the toddler alone. Between 18 and 36 months, the autonomous self emerges as toddlers develop the ability for more differentiated and complex representations of the self in relation to others (Greenspan & Porges, 1984). The caregiver’s sensitivity to and tolerance for the toddler’s strivings for autonomy are necessary for successful resolution of this issue. Caregivers who feel rejected by their toddlers’ new demands as they strive for autonomous functioning may inhibit the emergence of autonomy in their children if they are not supportive of this process or are unable to set age-appropriate limits (Cicchetti & Lynch, 1995). Moreover, extended periods of psychological unavailability from parents have been associated with expectations for the continued inaccessibility of the attachment figure and a view of the self as unlovable (Bowlby, 1973; Cummings & Cicchetti, 1990; Egeland & Sroufe, 1981). The child may then respond to novel situations and relationships in accord with the representational models that have emerged from this initial relationship experience and, furthermore, may actively select situations that are consistent with this relationship’s goals (Sroufe, 1983).

The emergence of the development of self during early toddlerhood has traditionally been examined through in-

vestigations of visual self-recognition (M. Lewis & Brooks-Gunn, 1979). The capacity to recognize the rouge-marked self in the mirror emerges during the 2nd year of life and provides some insight into children's early self-concept. Although no differences have emerged in maltreated infants' ability for visual self-recognition as early as 18 months of age, evidence reveals that there are significant differences in their affective expressions upon viewing the self. Specifically, maltreated children are more likely to display neutral or negative affect in response to their rouge-marked self (Schneider-Rosen & Cicchetti, 1984, 1991) than are nonmaltreated children. Therefore, it seems that although maltreatment does not impede the cognitive maturation necessary for the development of self-recognition, there are observable affective differences in the self-representations of maltreated toddlers.

At 24 months of age, a tool-use paradigm has been used to measure children's emerging autonomy, independent exploration, and ability to cope with frustration (Egeland & Sroufe, 1981). During this problem-solving interaction, maltreated children become more angry, frustrated with the mother, and noncompliant than do nonmaltreated children of similar SES, thereby suggesting that maltreated children experience difficulty in developing an autonomous self.

Moving into late toddlerhood, the ability to talk about the self, label emotions, and discuss feelings of self and other emerges, allowing for observations of more overt expressions of self-representation. Self-other differentiation can be reflected in children's self-descriptions, use of personal pronouns, and active agency during symbolic play (Beeghly & Cicchetti, 1994; Kagan, 1981). During observations of mother-child play, delays in maltreated children's self systems have been noted through the analysis of verbal communicative abilities and internal state language. Specifically, maltreated children talk less about themselves and about their internal states than do nonmaltreated children, show less differentiation in their attributional focus, and are more context-bound in their use of internal state language (Beeghly & Cicchetti, 1994; Coster, Gersten, Beeghly, & Cicchetti, 1989). Among maltreated children, those with insecure attachments display the most compromised internal state language (Beeghly & Cicchetti, 1994).

The dearth of negative internal state expression that has been noted among maltreated children is consistent with reports that maltreated children may inhibit negative affect, especially in the context of their relationship with their caregiver (Crittenden & DiLalla, 1988; Koenig, Cicchetti, & Rogosch, 2000; Lynch & Cicchetti, 1991). As sug-

gested by Cicchetti (1991), the suppression of negative emotions may reflect an adaptive process for children in the context of a maltreating environment. Through the modification of their behavior, maltreated children may mitigate their parents' responses to, as well as their own anxiety surrounding, particular uses of language (i.e., language that reflects negative emotion, references to the self and the self's desires) that have previously resulted in negative consequences. Outside of this context, however, the inability to acknowledge negative emotional states may impede maltreated children's ability to display empathy toward their peers and engage in successful social relationships (Main & George, 1985; Troy & Sroufe, 1987).

The investigation of the expression of self-conscious emotions has also been utilized as a way to assess self-representation among maltreated preschool children (Alessandri & Lewis, 1996). During problem-solving tasks between mother and child, significant differences emerged between maltreated and nonmaltreated children in the expression of both pride and shame. Maltreated girls were identified as at particular risk for negative self-conscious emotions, showing much less pride and more shame as compared to maltreated boys and nonmaltreated comparisons. There were also significant differences in the emotional responsivity of maltreating and nonmaltreating mothers in response to their children's successes and failures. Specifically, maltreating mothers provided more negative feedback and negative affective displays, especially toward their daughters, which likely impacts their children's expression of self-conscious emotion. The fact that maltreated girls showed fewer pride behaviors toward success and more shame toward failure is particularly noteworthy considering that the degree of affect children attribute to their performance abilities is an important contributor to their feelings of self-worth, competence, and motivation for school (J. L. Aber & Allen, 1987; Cassidy, 1988). Thus, the differences in maltreated children's expression of self-conscious emotion may represent precursory evidence for the development of low self-esteem and internalizing psychopathology.

Indeed, a number of investigations of self-esteem among maltreated children have been conducted, describing maltreated children as lower in ego control and self-esteem as early as the preschool years (Egeland, Sroufe, & Erickson, 1983) and revealing that maltreated school-age children report lower self-concepts than do nonmaltreated children (D. Allen & Tarnowski, 1989; Oates, Forrest, & Peacock, 1985). A closer developmental analysis of maltreated school-age children's self-concepts, however, supports a shift in self-esteem patterns across ages. Young maltreated

children (ages 6 and 7) tend to demonstrate an inflated sense of self-competence and social self-efficacy, yet by ages 8 or 9 this overly positive sense of self is no longer present; instead, they perceive themselves as being less competent than do nonmaltreated children (Kim & Cicchetti, 2003; Vondra et al., 1989). Corroboration of children's self-evaluations with teachers' ratings reveals that children's perceptions may in fact become more accurate and realistic as they grow older and view themselves in a more negative light.

Therefore, it seems that the experience of the school environment may have multiple implications for maltreated children's sense of self and subsequent relationships. As noted previously, exposure to school may provide maltreated children with their first experience of nonthreatening relationships, thereby facilitating the development of more secure relatedness. During the young school-age period, maltreated children tend to develop inflated levels of perceived self-efficacy in peer interactions, which has been identified as a protective factor in the pathways to internalizing symptomatology (Kim & Cicchetti, 2003). However, it is possible that this exaggerated sense of self is reflective of deficits in social information processing. Maltreated children may misinterpret social cues in peer interactions and misunderstand their own role in peer conflict, resulting in an overly positive self-view (e.g., Crick & Dodge, 1996a, 1996b). These processing errors may decrease over time as children develop the capacity for social comparison and may gain a growing awareness of their social inefficacy (see later section on social information processing). Alternatively, young maltreated children's inflated self-concept may be related to immaturity in developing representational models that are derived from early attachment insecurity (Cassidy, 1988) or defensive processing, whereby maltreated children inhibit negative affect and exhibit false-positive affect (Beeghly & Cicchetti, 1994; Crittenden & DiLalla, 1988; Koenig et al., 2000). Such explanations are plausible considering that as maltreated children continue to mature in the context of peer relations, they begin to make more negative self-appraisals, which perhaps are more representative of their true models of the self (see section on peer relations for further discussion).

Clearly, maltreated children display a number of difficulties and maladaptive patterns in their struggle for autonomy and developing self. Their inability to discuss negative emotional states combined with their increasingly negative self-representations may exacerbate and contribute to their problems in self-other differentiation, as well as their abil-

ity for social information processing and the development of successful peer relationships.

Furthermore, child maltreatment experiences have been linked to pathology in self-definition and self-regulation (Fischer & Ayoub, 1994; Westen, 1994). Initial investigations of self system psychopathology focused on those who experienced the most extreme forms of maltreatment. For example, among girls who experienced chronic sexual abuse, a complex form of dissociation called "polarized affective splitting" has been noted (Calverley, Fischer, & Ayoub, 1994). More recent work, however, suggests that less heinous forms of maltreatment can lead to disruptions in self system processes and self-integration. The experience of traumatic abuse, beyond that specific to sexual abuse, can play a role in the etiology of dissociative disorders (Cole & Putnam, 1992). For example, using an observer report measure of dissociation for children, Putnam (1996) demonstrated that maltreated school-age children showed more dissociation than nonmaltreated children. To address questions regarding developmental pathways to dissociative symptomatology, a longitudinal prospective study of children at high risk for poor developmental outcomes was conducted with children between the toddler period and age 19 (Ogawa et al., 1997). The results of this study indicated that trauma, which was defined to include maltreatment, predicted levels of dissociation at all developmental periods. In particular, dissociation in the toddler-preschool period was predicted by physical abuse and neglect in infancy, and the severity and chronicity of trauma predicted future levels of dissociation.

Story stem narratives also have been used to determine the extent of dissociation in maltreated and nonmaltreated preschool-age children (Macfie, Cicchetti, & Toth, 2001b). In an initial investigation focusing on moral-conflictual themes in maltreated preschool children's narratives, maltreated children portrayed parents and children as responding less often, yet themselves as stepping into the story more often to relieve children's distress (Macfie et al., 1999). In a subsequent investigation, Macfie and colleagues (2001b) posited that dissociation might help to explain this finding that maltreated children were more likely to break the narrative frame to relieve children's distress themselves, suggesting that for maltreated children, the line between reality and fantasy is blurred in fearful situations. In an analysis of dissociative content in the narratives preschool children provided, maltreated children demonstrated more dissociation than nonmaltreated children, especially those who were physically abused and sexually abused. Additionally, different developmental trajectories

for maltreated and nonmaltreated children were identified such that dissociation increased over time for the maltreated children, whereas such increases were not observed among the nonmaltreated children.

Another investigation extended findings on dissociation in maltreated children by analyzing subtype differences and also by incorporating measures of internalizing and externalizing symptomatology (Macfie, Cicchetti, & Toth, 2001a). Although clinical-range dissociation was associated with the experience of physical abuse only, children who experienced sexual abuse, physical abuse, or neglect each demonstrated more dissociation than the nonmaltreated group. Moreover, maltreatment severity, chronicity, multiple subtypes, and internalizing and externalizing symptomatology were each related to dissociation. Thus, it seems that the experience of maltreatment places children at considerable risk for dissociative symptomatology, highlighting the extreme extent to which maltreatment may disrupt one of the most central tendencies of ontogenic development: self system integration and development.

SYMBOLIC DEVELOPMENT

A critical cognitive achievement of toddlerhood is the development of representational thought using symbols (Piaget, 1962; Werner & Kaplan, 1963). This ability is expressed through language and play, where children can represent their growing awareness of self and other, in addition to practicing and cultivating behaviors that may become integrated into more complex behavioral sequences and problem-solving skills (Bruner, 1972; Cicchetti, 1990). Although the development of these symbolic capacities is largely a cognitive maturational process, representational thought does not emerge in isolation from socioemotional and environmental factors. In fact, as children develop the cognitive capacity for symbolic thought, ongoing relationships and experiences influence the organization and content of the representational models as they emerge. Representational models, and children's ability to manipulate them, may influence later cognitive processing abilities as well as social information-processing skills (Cicchetti & Lynch, 1995; Dodge et al., 1997).

Language

Although the capacity for language is highly canalized, a number of environmental factors are associated with the development of children's language competence, including socioeconomic status, maternal interactive behavior, and

maternal psychosocial functioning (Eigsti & Cicchetti, 2004; Morisset, Barnard, Greenberg, Booth, & Spieker, 1990). Maltreatment, especially severe neglect, is related to linguistic delays affecting both receptive and expressive language (R. E. Allen & Oliver, 1982; Culp, Watkins, & Lawrence, 1991; L. Fox, Long, & Langlois, 1988). These language deficits are associated with caretaking environments where maltreating parents fail to provide adequate social language exchange and direct verbal teaching (Culp et al., 1991; Wasserman, Green, & Allen, 1983). Attachment security also plays a role in the development of communicative competence such that secure attachment may operate as a protective factor for language competence among maltreated children (Gersten, Coster, Schneider-Rosen, Carlson, & Cicchetti, 1986). However, the preponderance of atypical attachment security among maltreated children (Barnett et al., 1999) places them at significant risk for maladaptive language development.

In an analysis of communicative functioning, Coster and colleagues (1989) identified multiple signs of language impairment among maltreated children. For example, maltreated children demonstrated shorter mean length utterances and more limited expressive, but not receptive, language. Additionally, analysis of the pragmatic use of language suggested that maltreated toddlers, along with their mother, have developed an interaction style in which language predominantly functions as a medium to accomplish tasks rather than as a medium for social or affective exchanges. Considering the findings that maltreated children also produce less internal state speech (Beeghly & Cicchetti, 1994; Coster et al., 1989) and less contingent speech (Coster et al., 1989), the evidence converges to suggest that the development of language among maltreated children occurs to the neglect of its potential use as a medium for social or affective discourse. Maltreated children's deficits in the pragmatic use of language for social sharing may present further challenges in their ability to develop close relationships and feel a sense of belongingness in later peer group formations.

The vast majority of language studies with maltreated children have focused on the content rather than the form of language, or used qualitative rather than quantitative measures of communicative abilities. To address this gap in the literature, Eigsti and Cicchetti (2004) examined the syntactic complexity of language among mother-child dyads from maltreating and nonmaltreating families. Child maltreatment was associated with quantitative language delays both in vocabulary and production of syntactic structures. Maltreating mothers' utterances, however, were

different in qualitative nature such that maltreating moms directed fewer utterances toward their children and produced fewer specific types of utterances (multiclausal utterances and yes/no questions), consistent with previous work regarding maternal verbal attention-directing behaviors (Alessandri, 1992). Furthermore, maternal expansions and repetitions were related to child age among dyads from nonmaltreating families, but not from maltreating families. This suggests that the mothers from maltreating families were less responsive to child-specific factors as they failed to tailor the age-appropriateness of their verbal behaviors. Additionally, this investigation represents the first demonstration of child language delays and differences in maternal speech in a single maltreated sample.

Play

Play is one of the most significant tasks of child development as it requires the integration of cognitive, motivational, emotional, and social skills. Through play, children develop and practice the skills and strategies that can be later used in goal-directed activities (Weisler & McCall, 1976). Though the structure of play is cognitively based (Belsky & Most, 1981; Nicolich, 1977), the motivation behind play is affective in nature (Hesse & Cicchetti, 1982). Mastery motivation and other stylistic aspects of play such as engagement in play and quality of exploration have been associated with more mature forms of object play (Fein & Apfel, 1979). Higher cognitive levels of play are associated with self-control, low impulsivity, and low aggression (Singer, 1976). Furthermore, it has been demonstrated that play can be used as a window onto the social understanding of children, with the development of symbolic play in particular reflecting children's emerging conceptions of themselves and of others (Beeghly, Weiss-Perry, & Cicchetti, 1990; Bretherton, 1984; Cicchetti, 1990).

In an investigation of mother-child play and social competence among 12-month-old infants, Valentino, Cicchetti, Toth, and Rogosch (in press) noted that although no differences emerged in the average level or maximum level of play complexity achieved, differences in play style, as assessed through social interaction behaviors, were prominent between infants from maltreating and nonmaltreating families. Specifically, infants from abusing families exhibited more imitation during play than did the infants from nonmaltreating families. Infants from abusing families also engaged in less independent play than both the infants from neglecting families and the infants from nonmaltreating families. Additionally, mothers differed in their interactions during mother-child play such that mothers from

abusing families demonstrated fewer attention-directing and limit-setting behaviors than did mothers from nonmaltreating families. Further analysis revealed that maternal attention-directing behaviors significantly predicted child play style behaviors but did not mediate the unique effects of maltreatment. Nonetheless, the differences in play style demonstrated by infants from abusing families represent the earliest indication of deviation in the development of sociocommunicative competence among maltreated children and suggests that these infants may already be at risk for atypical developmental pathways as young as 12 months of age (Valentino et al., in press).

Among preschool-age children, investigations of social play patterns have revealed that the play of maltreated children is both less cognitively mature and less socially mature than that of nonmaltreated children (Alessandri, 1991). Maltreated children spent less time engaged in play and more time in transition between play activities. Furthermore, most of their play was sensorimotor and functional, engaging in simple motoric activities and demonstrating greater touching of toys without any direct manipulations in both solitary and parallel social situations. In contrast, nonmaltreated children engaged in more cognitively mature and goal-oriented constructive play. The rates of dramatic play between maltreated and nonmaltreated children were comparable; however, the maltreated children demonstrated a restricted range of thematic content in their play. For example, maltreated children were much more imitative and likely to reenact everyday routines, and the nonmaltreated children were able to engage in more fantasy play; this is consistent with the differences noted among the play styles of infants from maltreating families during mother-child play at 12 months of age (Valentino et al., in press). Therefore, maltreatment does not seem to impede the cognitive maturation necessary for symbolic play. Rather, maltreatment's effects on play are manifest in the qualitative content of the play themes, a trend that is similar to differences noted among maltreated children's affective displays following self-recognition (Schneider-Rosen & Cicchetti, 1984, 1991).

In an additional investigation of maltreated preschool children's play behaviors, Alessandri (1992) demonstrated that differences in maltreated and nonmaltreated children's play are correlated with differences in mother-child interaction styles. Irrespective of maltreatment history, children who were exposed to low levels of maternal attention-directing behavior and to an aloof and critical mother were less likely to engage in higher forms of cognitive play, whereas those with mothers who focused their children's attention on objects and events and interacted in reciprocal

manner were able to initiate, maintain, and engage in more complex forms of cognitive play. Mothers from maltreating families were more controlling and less involved with their children, used fewer physical and verbal strategies to direct their children's attention, and were more negative in comparison with nonmaltreating mothers. Taken together, these three studies elucidate the deleterious impact that behaviors associated with maltreating parents may have on the development of their children's play, especially with regard to the content and style of these play behaviors.

Representational Models

Mental representational models are believed to play a guiding role in the continuity of development. Emerging from early attachment relationships, which become internalized as the first representations of self and other, representational models foster the maintenance of developmental trajectories as they organize expectations and schemas for relationships (Bowlby, 1969/1982; Cicchetti & Toth, 1995; Lynch & Cicchetti, 1991; Sroufe, 1989). Among normative samples, the quality of children's attachment relationships to the primary caregiver is associated with the complexity of their knowledge of self and others (Pipp et al., 1992).

Self-other differentiation and understanding are necessary, however, before one can build representational models of the self and other. Investigations of false belief understanding suggest that the capacity for mentalizing, or theory of mind (ToM), an understanding that another can have a perspective that is different from one's own, is reflective of the ability to differentiate between the self and other as distinct entities with separate mental states. The capability of understanding that different people can have different perspectives about a single situation is an essential development in the ability to predict people's behavior across settings; thus, false belief understanding is often interpreted as an indication of a representational theory of mind (Perner, 1991). Though most commonly associated with the development of children with Autism, ToM deficits have also been observed among various other atypical populations, such as children with Down syndrome, children with mental retardation of undifferentiated etiology, and children with deafness (Cicchetti & Beeghly, 1990; Fowler, 1998; Pennington & Bennetto, 1998; C. C. Peterson & Siegal, 1995, 1999). In accord with the principle of equifinality (Cicchetti & Rogosch, 1996), C. C. Peterson and Siegal (2000) argue that there may be multiple pathways to the development of ToM deficits besides the innately damaged neurobiological module often proposed to explain the poor performance of children with Autism

on false belief tasks. Specifically, they assert that for other populations of children, there may be a critical threshold level of environmental input that must be reached to initiate the neurobiological processes necessary for the development of ToM. For example, among late-signing deaf children, a lack of conversational input during early development may account for later deficits in the development of ToM (C. C. Peterson & Siegal, 1999).

Given the clear deviations in the average expectable environment that characterize the early development of maltreated children, it is likely that maltreated children would also be at increased risk for ToM deficits. To investigate the impact of family contextual influences on ToM development, Cicchetti, Rogosch, Maughan, Toth, and Bruce (2003) investigated false belief understanding among low SES maltreated and nonmaltreated and middle SES nonmaltreated children. Among maltreated children, deficits in false belief understanding were noted such that the occurrence of maltreatment during the toddler period, and physical abuse in particular, was associated with delay in development of ToM (Cicchetti et al., 2003). These delays in the capacity for self-other differentiation may place maltreated children at increased risk for the development of maladaptive representational models.

Representational models are particularly important because once early attachment models are internalized, they may guide subsequent interpersonal relationships as event schemas (Bretherton, 1990). Therefore, internal representational models of early attachment relationships organize expectations about other potential social partners as well as the self in relation to them (Crittenden, 1990). Given the paucity of secure attachment organization among maltreated children, they may develop negative expectations of how others will behave and of how successful the self will be in relation to others (Bowlby, 1973, 1980; Bretherton, 1991; Cicchetti, 1991; Lynch & Cicchetti, 1991). Continuity in children's relationship patterns with parents, siblings, friends, and teachers are well documented; for example, children's attachment quality with their mother is related to quality of attachment with their father (N. A. Fox, Kimmerly, & Schafer, 1991), siblings (Teti & Ablard, 1989), preschool friends (Park & Waters, 1989), and teachers (C. Howes & Hamilton, 1992). Specific to maltreated children, quality of attachment to foster parents tends to be consistent with the attachment quality that would be expected toward the maltreating mother (C. Howes & Segal, 1993). Additionally, maltreated children's patterns of relatedness to their mother significantly impact their feelings of relatedness to others (Lynch & Cicchetti, 1991) and are concordant with their patterns of relatedness to teachers, peers,

and best friends (Lynch & Cicchetti, 1992). These observed continuities in the quality and pattern of children's interactions across relationships lend support to the notion of enduring attachment organization, manifest in children's increasing use of organizing mental representations.

Direct research assessing maltreated and nonmaltreated children's representational models has flourished in the past decade. Initial research identifying differences between maltreated and nonmaltreated children's representational models emerged from the analysis of the complexity and organization of their person concepts, demonstrating that a child's pattern of relatedness to a particular person is significantly related to the descriptiveness, depth, evaluative consistency, and emotional tone of his or her open-ended description of that relationship figure (Cicchetti & Lynch, 1995). Further, children with optimal patterns of relatedness have relatively detailed conceptions of others that are associated with consistently positive affect, as opposed to the person concepts of children with nonoptimal patterns of relatedness (Cicchetti & Lynch, 1995).

Most recently, children's story stem narratives have been utilized as a medium for the assessment of representational models, beginning with a seminal paper by Toth, Cicchetti, Macfie, and Emde (1997). Analysis of the narratives of maltreated and nonmaltreated children revealed a complex pattern of distortions in the mental representations of maltreated children. Overall, the narratives of maltreated children contained more negative maternal representations and more negative self-representations than the narratives of the nonmaltreated children. Further examination of subtype differences revealed that physically abused children had the most negative maternal representations and more negative self-representations than the nonmaltreated children. Physically abused children had high levels of negative self-representations, and the neglected children emerged with low levels of positive representations compared to nonmaltreated children. This finding may be consistent with the lack of positive attention that characterizes neglected children's home environment, which may impede their overall development of self. Toth and colleagues conjectured that although physically abused children have experienced much negative parenting dysfunction, they may also have had periods when they were responded to positively (thus enabling positive self-representations). Sexually abused children manifested more positive self-representations than neglected children, which might be consistent with notions of a false self. This explanation seems plausible considering that their negative self-representations were comparable to the physically abused children's.

Extending their prior work to examine representations of caregiver and self over time, Toth, Cicchetti, Macfie, Maughan, and VanMeenen (2000) conducted a longitudinal investigation with maltreated and nonmaltreated preschoolers and found that maltreated children had more negative representations of parents and of self at the conclusion of the 1-year study period. Maltreated children also concurrently exhibited indices of negative and grandiose self-representations, which may be reflective of earlier attachment disorganization. Over time, maltreated preschool children displayed more grandiose self-representations, and nonmaltreated children displayed an opposite pattern. These findings are consistent with the exaggerated sense of self-competence and social self-efficacy that have been noted among young maltreated school-age children (Kim & Cicchetti, 2003; Vondra et al., 1989). By age 8 or 9, however, maltreated children's perceptions of self decrease such that they view themselves as less competent than nonmaltreated children; similarly, one might expect to see a comparable decline in maltreated children's self-representations as they progress into later childhood.

Derived from the early attachment relationship, children's mental representations of their caregivers should consolidate and generalize to form an organizing schema through which subsequent relationships may be interpreted. Therefore, in theory, children's mental representations of caregivers will influence their ability to engage in peer relationships. To assess the relationship between such mental representations and children's peer relationships, Shields, Ryan, and Cicchetti (2001) assessed maltreated and nonmaltreated children's narrative representations of caregivers and emotion regulation as predictors of later rejection by peers. Consistent with an organizational perspective of development, positive and coherent representations of caregivers were related to prosocial behavior and peer preference, whereas maladaptive representations were associated with emotion dysregulation, aggression, and peer rejection. Furthermore, mental representations mediated maltreatment's effects on peer rejection in part by undermining the ability for competent emotion regulation. Thus, mental representations of caregivers serve an important function in the development of peer relationships of at-risk children, in addition to the development of emotion regulation (see later sections on emotion regulation and peer relationships).

MORAL DEVELOPMENT

Alongside the development of representational models, an additional task of the preschool period is the development of

self-regulatory mechanisms. Internalization of moral standards enables the child to shift from external to internal control. The facilitation of internalization in young children is largely reliant on the caregiver (Ryan, Deci, & Grolnick, 1995) and is fostered through autonomy-supportive parental behaviors such as conveying choice, acknowledging the child's feelings, and providing a meaningful rationale for limitations that are set (Deci, Egharri, Patrick, & Leone, 1994; Ryan et al., 1995).

In contrast to those behaviors that promote the development of internalization in children, maltreating mothers tend to rely more on punitive and power-assertive strategies and less on reasoning and positively oriented strategies to discipline their children than do nonmaltreating mothers (Oldershaw et al., 1986). Additionally, maltreating parents tend to have overly high expectations for their children, a low tolerance for misbehavior, and a greater expectancy for compliance than do nonmaltreating parents (Chilamkurti & Milner, 1993; Dixon, Hamilton-Giachritsis, et al., 2005; Reid et al., 1987). Considering the maladaptive discipline strategies parents employ when their children fail to meet their unrealistically high expectations, it follows that maltreated children are likely at risk for maladaptive moral development.

Initial efforts to assess the moral development of maltreated children focused on children's moral judgments and reasoning (Smetana, Kelley, & Twentyman, 1984; Smetana et al., 1998, 1999). Differences in moral maturity were not found between maltreated and nonmaltreated children; all children evaluated moral transgressions as very serious, punishable, and wrong in the absence of rules. Differences did emerge, however, in the children's affective responses to moral transgression as a function of maltreatment subtype and gender (Smetana et al., 1998). For example, physically abused male perpetrators reported more anger in actual situations than did females, and physically abused females reported more happiness in response to actual transgressions than did physically abused males; this latter finding is perhaps consistent with an emerging false self. In contrast, neglected children reported less sadness than nonmaltreated children when judging how hypothetical perpetrators would feel and more fear in response to the hypothetical instances of unfair resource distribution than did the physically abused or nonmaltreated children.

In an additional investigation, Smetana and colleagues (1999) assessed the effects of provocation on maltreated and nonmaltreated preschoolers' understanding of moral transgressions. Consistent with their prior study, no gender or maltreatment status differences in ratings of transgression severity and deserved punishment were found; instead,

differences emerging as a function of maltreatment subtype were noted among children's affective responses. Overall, evidence demonstrates that maltreated and nonmaltreated children may differ in the organization of their affective responses rather than in their moral evaluations. This profile of functioning is consistent with observations of maltreated children's visual self-recognition behaviors, in addition to the qualitative aspects of their symbolic play, such that maltreatment's effects are more salient in the affective realm (Alessandri, 1991; Schneider-Rosen & Cicchetti, 1984, 1991).

There are disadvantages, however, in the methodology employed in the aforementioned investigations, such that directly asking children for moral judgments may influence children to answer in a manner that is socially appropriate, potentially in contrast to what they actually may believe. To address these concerns, a structured narrative storytelling task was utilized to assess representations of moral-affiliative and conflictual themes among maltreated preschoolers (Toth, Cicchetti, Macfie, Rogosch, & Maughan, 2000) as narratives may be a more indirect method of assessment. Results indicated that the narratives of maltreated children contained more conflictual and fewer moral-affiliative themes than did the stories of the nonmaltreated children. Furthermore, conflictual representations partially mediated the relationship between maltreatment and later externalizing behavior problems, thus demonstrating the relationship between child maltreatment, children's organization of their life experiences, and their behavioral symptomatology.

Utilizing an alternative methodological strategy, the development of internalization in maltreated and nonmaltreated preschool children has been examined through the behavioral coding of child compliance/noncompliance behaviors during a mother-child interaction (Koenig, Cicchetti, & Rogosch, 2000). Results indicated that abused children exhibited less moral internalization than the nonmaltreated children. The neglected children did not significantly differ from the nonmaltreated children on their level of internalization; however, they displayed more negative affect. Moreover, the physically abused children engaged in a strategy of situational compliance, which is consistent with the compulsive compliant coping style that has been identified among maltreated toddlers (Crittenden & DiLalla, 1988) and involves the suppression of negative behaviors and immediate compliance with maternal demands. This behavioral pattern, in which children distort their own emotional responses, may contribute to a lack of need fulfillment, and has been associated with later difficulties in emotion regulation, the potential to develop a false self,

and risk for psychopathology (Cicchetti, 1991; Crittenden & DiLalla, 1988; Ryan et al., 1995).

Additionally, an assessment of maternal behaviors revealed that maltreated and nonmaltreated groups differed in the techniques that best predicted child internalization. For the nonmaltreated dyads, a lower level of maternal joy predicted internalization; in contrast, among maltreating dyads, less maternal negative affect enhanced the child's ability to internalize the task. Further analysis revealed that child behaviors were more strongly predicted by maternal control strategies among maltreated children as compared to nonmaltreated children, supporting the notion that maltreated children are more reactive to maternal expression. Hypervigilance to affective expressions of others may serve an adaptive function for maltreated children so that they can detect potential signals of punishment or abuse (Pollak et al., 1997; Rieder & Cicchetti, 1989); however, it may occur at the expense of an awareness of one's own internal states, thereby hindering the development of internalization and other self-regulatory mechanisms.

Further deviations have been noted among 5-year-old maltreated children's moral development. Previous investigations with maltreated children focused on the behavioral indices of morality such as aggression and comforting responses to peers' distress. Koenig et al. (2004) expanded on the limited knowledge of moral development in physically abused, neglected, and nonmaltreated children by examining children's engagement in rule violations and by incorporating measures of "moral emotions" such as empathy and guilt. Findings revealed that different maltreatment experiences differentially impact moral development such that physically abused children engaged in more stealing behaviors and neglected children engaged in more cheating behavior and less rule-compatible behavior compared to nonmaltreated children. Moreover, maltreatment status differences interacted with gender on a number of moral paradigms, suggesting that the development of prosocial behaviors and moral emotions is more affected by maltreatment in girls than in boys. In particular, physically abused girls showed less guilt and fewer prosocial behaviors than neglected girls. Delays in internalization or underinternalization were associated with early physical abuse among girls; however, neglected girls were overinternalized (Koenig et al., 2004). Consequently, abused girls may be at risk for externalizing psychopathology and antisocial behavior, and neglected girls may be at risk for lower self-esteem and depression.

Overall, the extant research suggests that the experience of maltreatment exerts a deleterious impact on the development of self-regulatory mechanisms such as inter-

nalization. Future research should further examine specific vulnerability and protective factors; negative maternal affective expression, physical abuse, and female gender have each been associated with deviations in the development of moral internalization among maltreated children. Furthermore, maladaptive internalization may be associated with emotion regulation difficulties as well as later internalizing and externalizing symptomatology, each of which may have negative consequences for maltreated children's ability to resolve salient issues at the subsequent stages of development.

SOCIAL INFORMATION PROCESSING AND THE FORMATION OF PEER RELATIONSHIPS

As children proceed through development, they may rely on their representational models to aid processing of social information in addition to contextual and environmental inputs, which also influence the way children interpret their experiences. For example, among children developing in normative contexts, the presence of negative affective conditions is associated with more frequent information-processing errors (Bugental, Blue, Cortez, Fleck, & Rodriguez, 1992). Consistent with these findings, deficits in children's information processing are seen in association with harsh and maltreating parenting (Dodge et al., 1990). In particular, children who have been physically abused are less accurate in encoding social cues, they tend to generate a higher proportion of aggressive responses to problematic social situations, they view aggression more favorably, and they exhibit a hostile attribution bias (Dodge et al., 1997; Prince & Van Slyke, 1991). Furthermore, maladaptive social information-processing patterns appear to mediate the relationship between the effects of harsh parenting on children's aggression (Weiss, Dodge, Bates, & Pettit, 1992).

Cognitive control functioning has been identified as one possible mechanism contributing to maltreated children's social information-processing deficits. Cognitive control refers to the capacity to maintain more differentiated, articulate perceptions of past and external stimuli and to detect nuances and differences in perceptual stimuli more accurately and readily (Rieder & Cicchetti, 1989; Rogosch, Cicchetti, & Aber, 1995). In particular, the cognitive control functioning of maltreated children is affected by the presence of aggressive stimuli such that maltreated children recall a greater number of distracting aggressive stimuli than do nonmaltreated children (Rieder & Cicchetti, 1989), and maltreated children readily assimilate these aggressive stimuli. These findings suggest that maltreated

children's information processing differs from that of non-maltreated children by utilizing more negative affect information at the expense of less cognitive efficiency and impaired task performance. Moreover, these biases toward aggressive stimuli are consistent with the attentional biases maltreated children demonstrate in response to demonstrations of anger (Pine et al., 2005; Pollak et al., 1997, 2001; Pollak & Kistler, 2002; Pollak & Sinha, 2002; Pollak & Tolley-Schell, 2003).

Early deviations in cognitive and affective processing may adversely affect the development of peer relationships among maltreated children. Evidence supports that cognitive control functioning partially mediates both the influence of maltreatment on later dysregulated behavior in the peer setting and the effect of physical abuse on later rejection by peers (Rogosch, Cicchetti, & Aber, 1995). Specifically, maltreated children evidenced early deviations in their understanding of negative affect as well as immaturity in their cognitive controls. Moreover, maltreated children showed lower social effectiveness and higher levels of undercontrolled and aggressive behavior in school. Leveling/sharpening, one aspect of cognitive control, was identified as a salient contributor to later social effectiveness with peers, whereas negative affect understanding was more related to problems in behavior control and aggressiveness and to peer rejection among abused children. These findings are consistent with an organizational/transactional model whereby early parent-child relationships lead to poor organization of cognitive and affective processes, which in turn affects peer relationships and social dysfunction.

Because maltreated children's early histories are marred by negative and dysfunctional relationships, the opportunity to develop peer relationships and friendships may help to promote positive adaptation in maltreated children (Cicchetti, Lynch, Shonk, & Manly, 1992). Many important issues of children's social and emotional development are facilitated through relatedness with peers and exposure to an extended social network (Parker & Herrera, 1996). Thus, the development of peer relationships represents an important stage-salient task for school-age children.

Unfortunately, maltreated children approach engaging in peer interactions with the maladaptive representational models they have developed through their early caregiving experiences. As a result, maltreated children's relationships with their peers typically mirror their maladaptive representational models. In general, maltreated children interact less with their peers, exhibit more disturbed patterns of engagement when they do interact, and display fewer prosocial behaviors than nonmaltreated children

(Haskett & Kistner, 1991; Hoffman-Plotkin & Twentyman, 1984; Jacobson & Straker, 1982).

To empirically investigate whether representations of caregivers serve an important regulatory function in the peer relationships of at-risk children, Shields et al. (2001) assessed children's representation of mothers and fathers and emotion dysregulation as predictors of children's rejection by peers. In support of this organizational account for the difficulties noted in maltreated children's peer relationships, maltreated children's representations of caregivers were more negative/constricted and less positive/coherent than those of nonmaltreated children; such maladaptive representations were associated with emotion dysregulation, aggression, and peer rejection, whereas positive/coherent representations were related to prosocial behavior and peer preference. Thus, children's caregiver representations mediated maltreatment's effects on peer rejection in part by undermining emotion regulation.

Additional investigations have highlighted the role of severity, chronicity, and age of onset of maltreatment in the extent to which maltreated children display general maladjustment and incompetence with their peers (Bolger et al., 1998). Specifically, early onset of maltreatment has been associated with greater impairments in children's self-esteem. For emotionally maltreated children in particular, age at onset moderated the effect of emotional maltreatment on children's adjustment such that emotionally maltreated children were less likely to have a reciprocated best friend if their maltreatment began early in life. With regard to chronicity, Bolger and colleagues revealed that children who experience chronic maltreatment were less well-liked by their peers. For example, maltreatment chronicity appeared to exacerbate the effect of abuse on the quality of physically abused children's friendships such that friendship quality declined as children's experiences of physical abuse increased in duration. In an additional prospective longitudinal investigation, Bolger and Patterson (2001) found further support for the notion that chronically maltreated children are likely to be rejected repeatedly across multiple years from childhood to early adolescence. Maltreatment chronicity was also associated with higher levels of aggressive behavior, which accounted in large part for the association between maltreatment and rejection by peers (Bolger & Patterson, 2001).

Maltreatment subtype has also been related to specific aspects of children's adjustment. For example, emotional maltreatment is related to difficulties in peer relationships but not to self-esteem, and the reverse pattern may be true for sexually abused children (Bolger & Patterson, 2001). Physically abused children are less popular with their

peers, show less positive reciprocity in their interactions, and have social networks that are more insular and atypical with higher levels of negativity (Dodge, Pettit, & Bates, 1994; Haskett & Kistner, 1991; Salzinger et al., 1993). Even more alarming is evidence that rejection of maltreated children by peers may increase over time (Dodge et al., 1997).

Overall, two general developmental trajectories characterize maltreated children's peer relationships (Cicchetti et al., 1992; Cicchetti & Lynch, 1995; Mueller & Silverman, 1989). One pathway leads to the development of physical and verbal aggression in maltreated children's interactions with their peers, such that children who have been physically abused may be at heightened risk (Bolger & Patterson, 2001; George & Main, 1979; R. C. Herrenkohl & Herrenkohl, 1981; Hoffman-Plotkin & Twentyman, 1984; Kaufman & Cicchetti, 1989; Salzinger et al., 1993). Even as early as preschool age, abused children are more likely than are nonabused children to cause distress in their peers (Klimes-Dougan & Kistner, 1990). Moreover, maltreated children have been observed to respond with anger and aggression even to friendly and nonthreatening gestures from their peers (C. Howes & Eldredge, 1985).

The second developmental pathway leads to passive withdrawal as well as active avoidance behaviors that have been noted among maltreated children in the context of peer interactions; this may be especially prevalent among those who have been neglected (Dodge et al., 1994; George & Main, 1979; Hoffman-Plotkin & Twentyman, 1984; C. Howes & Espinosa, 1985; Jacobson & Straker, 1982). Withdrawn behavior is associated with poor peer outcomes; however, it may not account for the relationship between maltreatment and peer rejection (Bolger & Patterson, 2001). Rather, withdrawn behavior may be a function of maladaptive social expectations regarding peers (Salzinger, Feldman, Ng-Mak, Mojica, & Stockhammer, 2001), which has a more direct impact on children's peer relationships. Specifically, Salzinger and colleagues found that children's social expectations regarding peers mediated the relationship between abuse and children's positive social status; withdrawn behavior also mediated this relationship, but only as a function of social expectations.

In addition to these two generally diverging pathways, a subgroup of maltreated and nonmaltreated children has been identified who demonstrate both aggressive and withdrawn behaviors (Rogosch & Cicchetti, 1994). Concomitant heightened aggressiveness and social withdrawal may lead to increasing social isolation and peer rejection (Rubin, LeMare, & Lollis, 1990; Rubin & Lollis, 1988). Among maltreated children, those who evidence high ag-

gression and high withdrawal demonstrate lower social effectiveness than is the case for nonmaltreated youngsters (Rogosch & Cicchetti, 1994). This unusual pattern of interaction with peers is consistent with the attachment history of maltreated children, which, characterized by disorganization, may be related to disorganized representational models and may result in disturbance in social encounters. By revealing indications of a predisposition to both "fight" and "flight" responses, maltreated children's interactions with peers lends support to the notion that these children have internalized both sides of their relationship with their caregiver (Troy & Sroufe, 1987). These findings are also consistent with the increased rates of bullying and victimization behaviors that have been noted among maltreated children (Shields & Cicchetti, 2001). Thus, maltreated children's representational models may have elements of both the victim and the victimizer, and these models may be enacted in their peer relationships.

Significant difficulties in cultivating and maintaining friendships have also been found among maltreated children (Parker & Herrera, 1996). Preadolescent and young adolescent physically abused children and their friends tend to display less intimacy in their interactions than do nonabused children and their friends. Friendships of physically abused children are more conflictual, especially during situations where emotion regulation skills are taxed, such as during competitive activities. However, evidence supports that if maltreated children can develop and maintain a close friendship, the presence of this relationship will be associated with improvement over time in self-esteem (Bolger et al., 1998).

Heightened aggressiveness, avoidance of and withdrawal from social interactions, and inappropriate responses to nonthreatening gestures render the development of effective relationships quite challenging for maltreated children. This maladaptive pattern of relationship histories represents yet another risk factor for negative developmental outcomes. For example, having poor peer relationships in childhood is associated with juvenile delinquency and other types of behavior disorders during adolescence (e.g., Cowen, Pederson, Babigian, Izzo, & Trost, 1973), as well as school dropout, criminality, delinquency, and psychological disturbance in adolescence and adulthood (Ollendick, Weist, Borden, & Greene, 1992; Parker & Asher, 1987; Rubin & Mills, 1988; Rubin & Ross, 1988). Each of the developmental pathways delineated may be associated with different maladaptive sequelae (Cicchetti et al., 1992). The aggression pathway may lead to the development of externalizing disorders as maltreated children's displays of hostility in relationships may lead to rejection by peer groups.

The experience of rejection may then turn children against the group and lead to the onset of externalizing problems. Providing support for this notion, a recent model of peer interactions proposed by Dodge et al. (2003) posits that initial processing biases and deficits lead to social rejection among children. The experience of social rejection (or lack of experience of positive peer relationships) then exacerbates processing biases and deficits that lead to aggressive behavior. The implications of this model are that social rejection by peers acts as a social stressor that increases the tendency to react aggressively among children who are so disposed, thus leading to a recursive model of antisocial development. Such a model is consistent with the chronic and repeated rejection by peers that has been noted among maltreated children (Bolger & Patterson, 2001).

In contrast, the withdrawn/avoidant pathway may lead to the development of internalizing problems. For example, children who react to the environment through withdrawal may also be viewed as deviant from age-appropriate norms, contributing to peer rejection. For these children, the experience of rejection may exacerbate social withdrawal and potentiate the development of internalizing problems.

ADAPTATION TO SCHOOL

Beginning in early childhood, the context of school is the major extrafamilial environment to which children are exposed. Beyond integration into peer groups, acceptable performance in the classroom and appropriate motivational orientations for achievement are important aspects of this stage-salient developmental task (Cicchetti & Lynch, 1995). Unsurprisingly, maltreated children appear to be at risk for unsuccessful resolution of these issues of development. Given evidence that children from high-risk samples with low socioeconomic backgrounds evidence a high percentage of difficulties at school (Egeland & Abery, 1991), maltreated children appear to be at heightened risk for maladjustment at school as a function of their socioeconomic status, apart from the effects of maltreatment. Compared to nonmaltreated children of similar socioeconomic backgrounds, however, maltreated children receive more discipline referrals and suspensions (Eckenrode & Laird, 1991; Eckenrode, Laird, & Doris, 1993) and are more dependent on their teachers (Egeland et al., 1983). Maltreated children perform worse on standardized tests, achieve lower grades, and are more likely to repeat a grade. Furthermore, they score lower on tests that assess cognitive maturity. However, it is unclear whether these difficul-

ties can be attributed to cognitive or motivational issues (Barahal, Waterman, & Martin, 1981).

With regard to motivation, J. L. Aber and Allen (1987) proposed that effectance motivation, which is the intrinsic desire to deal competently with one's environment, and successful relations with novel adults are important factors related to children's ability to adapt to their first major out-of-home environment. As such, they defined the concept of "secure readiness to learn" as characterized by high effectance motivation and low dependency, as a representation for the ability to establish secure relationships with adults while feeling free to explore and engage in the environment in ways that promote cognitive development. Maltreated children score lower on secure readiness to learn than do nonmaltreated children (J. L. Aber & Allen, 1987; J. L. Aber et al., 1989), which is consistent with what one might expect given the insecurity or atypicality that pervades maltreated children's attachment histories (Barnett et al., 1999).

To further assess the impact of relationships with caregivers on children's school functioning, Toth and Cicchetti (1996) examined the role of children's relationships with their mother in school adaptation. Nonmaltreated children who reported optimal/adequate relatedness to their mother (conceptually comparable to secure attachment) exhibited fewer school record risk factors as well as less externalizing symptomatology and more ego resilience than did maltreated children who reported nonoptimal patterns of relatedness. Thus, in the nonmaltreated group, optimal/adequate patterns of relatedness exerted a positive effect on multiple aspects of school functioning. However, in the maltreated group, optimal/adequate relatedness exerted a positive effect only on school records. Moreover, according to teacher-rated externalizing and social acceptance, maltreated children with nonoptimal patterns of relatedness evidenced more positive adaptation than maltreated children with optimal/adequate relatedness. Possible explanations for these findings include the potential role of defensive processing, in which child self-reported relatedness may be invalid such that insecurely attached children report being more secure, and the possible negative effect of having a positive relationship with a maltreating caregiver. Finally, the compulsive-compliant strategy that has been noted among maltreated children during interactions with their mother (Koenig et al., 2000) may be relevant here, such that the teacher's reports of compliant behavior may not be adequate to capture underlying maladaptation. The results highlight the complex role played by the child's representation of the primary caregiver in affecting school adaptation.

Nonetheless, maltreated children appear to display academic deficits, and a number of studies have suggested that the various subtypes of maltreatment may exert specific effects on children's academic competence. For example, several investigations have found that neglected children display the most severe academic deficits (Eckenrode et al., 1993; Wodarski, Kurtz, Gaudin, & Howing, 1990) in comparison to children who have experienced other maltreatment subtypes. In contrast, sexually abused children appear to be socially passive, excessively dependent on the teachers, and lacking autonomy in their school functioning (M. K. Erickson, Egeland, & Pianta, 1989). Additionally, studies specifically investigating the relation of sexual abuse to cognitive ability have found that sexually abused girls demonstrate poorer overall academic performance and receive more negative ratings of classroom social competence than do girls with no history of sexual abuse (Trickett, McBride-Chang & Putnam, 1994).

In assessments of social competence, teachers consistently perceive maltreated children as evidencing greater disturbance in social functioning than nonmaltreated children (Cicchetti & Rogosch, 1994). Specifically, maltreated children are rated as less socially competent and less accepted by their peers and display higher levels of behavioral disturbance, particularly involving externalizing behaviors. Classroom peers also distinguish maltreated children as more rejected or isolated by peer groups, with physically abused children showing the greatest differentiation from their nonmaltreated peers. Observations of maltreated children and their response to the task of school entry (M. K. Erickson et al., 1989) have revealed that aggressive, noncompliant, acting-out behaviors are common among physically abused children. In contrast, neglected children appeared uncooperative with teachers and insensitive and unempathic with peers. Clearly, these deviations in social functioning contribute to the maladaptive processes that characterize maltreated children's functioning in school. Research examining the mechanisms through which maltreatment may impact children's academic adjustment considered the contribution of deficits in multiple areas of functioning (Shonk & Cicchetti, 2001). Specifically, deficits in social competencies, academic engagement, ego resiliency, and ego control were hypothesized to negatively predict children's academic and behavioral adjustment. The results of this investigation highlighted the pathways through which maltreatment affects different domains of children's adjustment by revealing that whereas the effects of maltreatment on academic maladjustment are mediated by academic engagement, maltreatment's effects

on behavior problems are fully mediated by social competencies and ego resiliency (Shonk & Cicchetti, 2001).

PERSONALITY ORGANIZATION

The extent of variation in personality characteristics and personality organization among maltreated children represents an area of investigation that has recently gained attention in the maltreatment literature. Given the vast array of developmental sequelae evidenced by maltreated children, this domain of development is likely to contribute to our understanding of differential vulnerability and resilience processes among maltreated youth (Rogosch & Cicchetti, 2004).

The application of temperament models has been prominent in characterizing individual differences among infants and young children (Rothbart, Posner, & Hershey, 1995). These models emphasized variation in behavioral characteristics that are presumed to be biologically based (Rothbart & Bates, 1998). As children proceed through development, the features of these temperamental systems are elaborated and consolidated into an individual's personality, as they are modified by environmental experiences (Kagan, 1994). Given the extreme failure of the average expectable environment that is associated with child maltreatment, one might expect maltreated children to manifest maladaptive personality organization.

To address the paucity of research on the personality development of maltreated children, Rogosch and Cicchetti (2004) utilized the five factor model (FFM) to study the emergent personality organization of maltreated children. The FFM approach is well established as a synthesizing descriptive system of personality that involves five primary personality dimensions: extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience (McCrae & John, 1992). Research on children using the FFM has taken a personality-centered approach to identify individuals exhibiting patterns of organization among the FFM dimensions. For example, by applying a factor-analytic strategy, Robins, John, Caspi, Moffitt, and Stouthamer-Loeber (1996) identified three personality configurations emerging from the FFM which they named resilient, overcontrollers, and undercontrollers.

In their longitudinal assessment, Rogosch and Cicchetti (2004) examined the personality organization of 6-year-old maltreated and nonmaltreated children who were then followed up at 7, 8, and 9 years of age. Results indicated that the 6-year-old maltreated children exhibited lower agree-

ableness, conscientiousness, and openness to experience and higher neuroticism than nonmaltreated children. Using a similar analytic approach to that of Robins and colleagues, five personality clusters emerged: overcontroller, undercontroller, reserved, dysphoric, and gregarious. The gregarious and reserved clusters taken together closely resemble the resilient organization noted in previous studies (both are adaptive personality organizations). Maltreated children, however, were more frequently represented in the less adaptive personality clusters (overcontroller, undercontroller, and dysphoric). One particularly vulnerable profile, dysphoric, emerged predominantly among maltreated children who had been both abused and neglected; this organization, which represents a newly identified personality cluster, was characterized by low conscientiousness, agreeableness, and openness to experience, with high neuroticism. The dysphoric cluster was rarely observed among nonmaltreated children, which may explain why it had not previously been identified (D. Hart, Hofmann, Edelstein, & Keller, 1997; Robins et al., 1996).

Overall, maltreatment and personality clusters were related to individual differences that were perceived by peers. Furthermore, continuity and stability of children's personality organization and personality liabilities were found such that personality clusters at age 9 were maintained from age 6. Thus, there is substantial vulnerability in the personality features of maltreated children, highlighting the need for interventions to promote competence and prevent the consolidation of maladaptive personality organization.

MALADAPTATION: THE EMERGENCE OF BEHAVIOR PROBLEMS AND PSYCHOPATHOLOGY

In keeping with the dynamic systems concepts of equifinality and multifinality (Cicchetti & Rogosch, 1996), multiple pathways to adaptation and maladaptation, as well as varied developmental outcomes, are possible for maltreated children. The ecological conditions associated with maltreatment represent a severe deviation from the average expectable environment. Without adequate environmental supports, the probabilistic path of ontogenesis for maltreated children is characterized by an increased risk for unsuccessful resolution of many stage-salient issues of development. Failure at any stage-salient task increases the risk of unsuccessful resolution of subsequent developmental challenges. As reviewed, maltreated children are likely

to exhibit atypicalities or deficits in neurobiological processes, physiological responsiveness, affect differentiation and regulation, attachment relationships, self-system processes, representational development, moral development, social information processing, peer relationships, adaptation to school, and personality organization. Furthermore, several continuities in maltreated children's patterns of maladaptation have become apparent; for example, disorganization in the early attachment relationship is reflected throughout subsequent stages of development, such as in children's aberrant representational models, parentified behaviors, bullying and victim internalizations, and concomitant aggression toward and withdrawal from peers. Other continuities include the apparent canalization of cognitive milestones in the face of maltreatment (e.g., the emergence of visual self-recognition, pretend play abilities), despite clear differences in affective displays accompanying such behaviors. Thus, maltreated children are at risk for developing a profile of relatively enduring vulnerability factors, placing them at high risk for future maladaptation (Cicchetti & Lynch, 1993).

Several long-term consequences to child maltreatment have been identified in adulthood (see Arnow, 2004, for review). However, the majority of research regarding the adverse outcomes of child maltreatment is limited by its reliance on retrospective reports (Brewin, Andrews, & Gotlib, 1993; A. V. Horowitz, Widom, McLaughlin, & White, 2001). For example, a retrospective study of homeless women found that childhood abuse has significant indirect effects on depression, chronic homelessness, and drug and alcohol problems, which are mediated through later physical abuse and self-esteem (J. A. Stein, Leslie, & Nyamathi, 2002). However, due to the use of retrospective methodology, it is difficult to determine causal links between abuse and later outcomes in adulthood. Given evidence that recollections of past abusive experiences may change over time in light of later events and changing definitions of abuse (Loftus, 1993), the reliability of findings of the long-term mental health effects of childhood abuse based on retrospective data has been subject to serious critique (Widom & Morris, 1997; Widom & Shepard, 1996). Furthermore, this technique is often applied to adult populations who have been identified as expressing a specific problem, thus bringing the generalizability of such findings into question.

Keeping in mind the limitations of retrospective analysis within specific pathological populations, the link between abuse and aggressive and violent behavior in adolescents and adults has been consistently documented in

the literature. For example, higher rates of physical abuse are reported among adolescents who have specified problems with violence and aggression (D. O. Lewis, Mallouh, & Webb, 1989), among adults who are convicted of violent offenses or who are institutionalized and have violent tendencies (M. Rosenbaum & Bennett, 1986; Sack & Mason, 1980), and among adults who engage in partner violence (Ehrensaft et al., 2003), as well as among those who experience revictimization in adulthood (A. J. Lang, Stein, Kennedy, & Foy, 2004).

A history of physical abuse has also been linked to other forms of psychological disturbance. For example, depressed inpatients who had been physically abused have demonstrated higher levels of impulsivity, aggression, and lifetime suicide attempts in comparison to nonabused depressed inpatients (Brodsky et al., 2001). Children who have been physically abused are at risk for suicidal ideation (Finzi et al., 2001; Thompson et al., 2005), and this risk may extend into adulthood (Dube et al., 2001). Research on suicidality among maltreated children suggests that profound interpersonal difficulties during middle adolescence may mediate the associations between child maltreatment and suicide attempts during late adolescence and early adulthood (J. G. Johnson et al., 2002). Providing further support for the centrality of proximal stressors in predicting maltreated children's risk for suicide, a study with maltreated adolescents suggested that the link between maltreatment and suicidality could be largely accounted for by risk factors such as family functioning and parent or child psychopathology (Kaplan et al., 1999). Among younger maltreated children (age 8), witnessed violence and child maltreatment, as well as child psychological distress, substance use, and poor social problem solving, have each been associated with suicide. The effects of maltreatment and witnessed violence on suicidal ideation, however, were mediated by child functioning (Thompson et al., 2005). Consistent with an organizational developmental perspective, prior experiences of maltreatment leave children with fewer resources to master new developmental tasks and to protect themselves against subsequent challenges, thereby increasing their vulnerability for suicide in the face of proximal stress.

Although the aforementioned investigations have identified a number of maladaptive long-term sequelae of child maltreatment, studies that are prospective and longitudinal in design are much more informative with regard to identifying individual developmental pathways to adaptation or maladaptation. For example, a prospective longitudinal study by A. V. Horowitz and colleagues (2001) indicated that

men and women who were physically abused and neglected as children had higher rates of Dysthymia and Antisocial Personality Disorder as adults than did matched controls. Women who had experienced abuse and neglect as children additionally endorsed more problems with alcohol abuse than did controls. Moreover, the abused and neglected groups reported not only more symptoms of psychopathology as adults, but also a greater number of lifetime stressors; these stressors accounted for much of the relationship between childhood abuse and adult mental health outcomes (A. V. Horowitz et al., 2001).

Among children, a longitudinal study conducted by Kim and Cicchetti (2004) demonstrated that maltreatment and mother-child relationship quality independently contributed to the development of children's internalizing and externalizing problems over time, both directly and indirectly through self-esteem and social competence. Specifically, maltreated children showed less socially adaptive behaviors with peers than the nonmaltreated children. Furthermore, maltreatment was related to internalizing and externalizing symptomatology, directly as well as indirectly through deficits in social competencies. Self-esteem mediated the impact of mother-child relationship quality on child adjustment outcomes for both maltreated and nonmaltreated children, such that secure attachment was negatively related to internalizing and externalizing at Time 2 (1 year later), via its influence on self-esteem at Time 1. Elevated internalizing and externalizing symptomatology is consistent with several additional studies showing that maltreated school-age children and adolescents manifest higher levels of depressed symptomatology, behavior problems at home and at school, and juvenile delinquency than do nonmaltreated children (Crittenden, Claussen, & Sugarman, 1994; Okun et al., 1994; Zingraff, Leiter, Myers, & Johnsen, 1993). Moreover, the maladaptive trajectories of maltreated children diverge from those of nonmaltreated children over time such that maltreated children's problems become more severe as children get older, especially in the domains of peer relationships and behavior problems such as aggression (Crittenden et al., 1994; Dodge et al., 1994).

Beyond general adjustment problems, maltreatment is associated with a higher prevalence of clinical-level psychiatric symptomatology and diagnoses than is observed among nonmaltreated children. For example, a significantly higher incidence of Attention-Deficit/Hyperactivity Disorder, Oppositional Defiant Disorder, and Posttraumatic Stress Disorder was found among maltreated children than nonmaltreated children, according to both the parent and child administrations of the Diagnostic Inter-

view for Children and Adults (Famularo, Kinscherff, & Fenton, 1992). The child interviews revealed higher incidence of psychotic symptoms as well as personality and adjustment disorders, and the parent interviews indicated a greater incidence of conduct and mood disorders among maltreated children (Famularo et al., 1992). Physical and sexual abuse in particular have been related to a number of psychiatric disorders in childhood and adulthood, including panic disorders, anxiety disorders, depression, eating disorders, somatic complaints, dissociation and hysterical symptoms, sexual dysfunction, and Borderline Personality Disorder (A. Browne & Finklehor, 1986; Kessler, Davis, & Kendler, 1997; Merry & Andrews, 1994; Putnam, 2003; Weaver & Clum, 1993; Wolfe & Jaffe, 1991).

In general, research has largely focused on the role of maltreatment in the development of depression, Posttraumatic Stress Disorder, dissociative disorders, and personality disorders. Elevated rates of depressive symptomatology are consistently found among maltreated children in comparison to nonmaltreated children (Kim & Cicchetti, 2004; Sternberg et al., 1993; Toth & Cicchetti, 1996; Toth, Manly, & Cicchetti, 1992). Additionally, many maltreated children meet diagnostic criteria for Dysthymia (Kaufman, 1991). A variety of factors have been posited to mediate the impact of maltreatment on depression: subtype of maltreatment, children's patterns of relatedness to their mother, social support and stressful life events, attributional styles, social competence and self-esteem, and psychophysiology (Kaufman, 1991; Kim & Cicchetti, 2004; Koverla, Pound, Heger, & Lytle, 1993; Toth & Cicchetti, 1996; Toth et al., 1992; Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002). For example, the relationship between cognitive style and subtype of maltreatment has been associated with the development of both nonendogenous depression and hopelessness depression in adulthood (Gibb, Wheeler, Alloy, & Abramson, 2001). Specifically, levels of child emotional maltreatment, but not physical or sexual abuse, have been related to levels of hopelessness and episodes of nonendogenous Major Depression and hopelessness depression. Evidence from this retrospective analysis supports that the presence of a negative cognitive style partially mediates the relationship between childhood emotional maltreatment and nonendogenous Major Depression and fully mediates the relation between emotional maltreatment and hopelessness depression (Gibb, Wheeler, et al., 2001). In an investigation of the relationship between child maltreatment, cognitive style, and depression, Toth, Cicchetti, and Kim (2002) concurrently assessed cognitive styles and

behavioral internalizing and externalizing symptomatology among maltreated and nonmaltreated school-age children. Children's attributional style emerged as a significant moderator of the relationship between maltreatment and externalizing symptoms, suggesting that attributional style may exert a protective effect against the negative consequences of maltreatment. Moreover, results indicated that children's perceptions of their mother functions as a mediator between maltreatment and the development of internalizing and externalizing symptomatology. Specifically, the findings support that maltreatment is related both directly and indirectly to behavioral maladjustment. The indirect pathway suggests that maltreatment contributes to children's forming less positive perceptions of their mother, which then exacerbates internalizing and externalizing psychopathology (Toth, Cicchetti, & Kim, 2002).

Alternatively, the experience of sexual abuse has been associated with an increased likelihood of impairments in a number of interrelated areas of development, including the development of self-esteem and self concepts; beliefs about personal power, control, and self-efficacy; the development of cognitive and social competencies; and emotional and behavioral self-regulation (Putnam & Trickett, 1993). A recent review of all published literature between 1989 and 2003 containing empirical data relevant to childhood sexual abuse found that depression in adulthood and sexualized behaviors in children are the best-documented outcomes of child sexual abuse (Putnam, 2003). For example, in a recent investigation among a sample of depressed women, those with and without a history of sexual abuse were comparable regarding the severity of depression; however, the women with child sexual abuse history were more likely to have attempted suicide and/or engaged in deliberate self-harm (Gladstone et al., 2004). Thus, depressed women with a history of sexual abuse may constitute a subgroup of patients who may require tailored interventions to battle depression recurrence and harmful and self-defeating coping strategies.

Kendler, Kuhn, and Prescott (2004) examined whether childhood sexual abuse (CSA) in women altered sensitivity in adulthood to the depressogenic effects of stressful life events (SLEs). Utilizing a population-based sample of 1,404 female adult twins, Kendler and colleagues found that previously assessed neuroticism and CSA and past-year SLEs predicted Major Depressive Disorder. Moreover, women with severe CSA had an increased risk for Major Depression and an increased sensitivity to the depressogenic effects of SLEs. These findings illustrate that early

environmental risk factors, just as is the case with genetic factors, can produce long-term increases in the sensitivity of women to depressogenic life experiences.

Posttraumatic Stress Disorder (PTSD) develops in response to the occurrence of a major stressor and is characterized by frequent reexperiencing of the traumatic event through flashbacks, nightmares, or intrusive thoughts; a numbing of general responsiveness to current events; and persistent symptoms of increased arousal (American Psychiatric Association, 1987, 1994). The experience of childhood sexual abuse has been related to the development of immediate as well as long-term PTSD symptoms (Briere & Runtz, 1993; McLeer, Callaghan, Henry, & Wallen, 1994). Furthermore, children who have been sexually abused experience PTSD at rates higher than children who have experienced other subtypes of maltreatment (Deblinger, McLeer, Atkins, Ralphe, & Foa, 1989; Kendall-Tackett, Williams, & Finkehor, 1993; Kiser, Heston, Millsap, & Pruitt, 1991; Merry & Andrews, 1994).

Dissociation refers to a psychological phenomenon manifest by a disruption in the normally self-integrative processes of memory, identity, and consciousness (American Psychological Association, 1987, 1994). Dissociation states range on a continuum from normal minor occurrences of everyday life, such as daydreaming, to pathological manifestations such as that seen in Multiple Personality Disorder and fugue states (Fischer & Ayoub, 1994; Putnam & Trickett, 1993; Westen, 1994). Given the severe disruptions in self system development, including dissociative symptoms, that have been observed among maltreated children (Macfie et al., 2001a, 2001b), it follows that these children would be at risk for later emergence of dissociative psychopathology.

Sexual abuse in particular has been associated with dissociation, conceptualized clinically as a defensive process against overwhelming trauma (M. R. Nash, Hulsey, Sexton, Harralson, & Lambert, 1993). Higher rates of dissociation and splitting are seen among sexually abused children than in any other comparison group (Calverley et al., 1994; Kirby, Chi, & Dill, 1993; M. R. Nash et al., 1993). Further, there seems to be a unique relationship between sexual abuse and dissociation that is not present for physical abuse such that dissociation has been shown to have an important mediating role between sexual abuse and psychiatric disturbance (Kisiel & Lyons, 2001).

In a recent investigation, childhood interpersonal trauma as a whole was highly predictive of a diagnosis of Depersonalization Disorder and of scores denoting dissociation, pathological dissociation, and depersonalization (Simeon, Guralnik, Schmeidler, Sirof, & Knutelska, 2001). When an-

alyzing the effects of specific subtypes of trauma, emotional abuse alone emerged as the most significant predictor of both Depersonalization Disorder diagnosis and severity; it did not, however, predict general scores denoting dissociation. General dissociation scores were best predicted by the combined severity of emotional and sexual abuse. This suggests that a unique relationship may exist between emotional abuse and Depersonalization Disorder, whereas other subtypes or combinations of abuse may contribute to more severe dissociative symptoms.

Personality disorders are conceptualized as rather enduring, character-based patterns of pathology that emerge in adolescence or early adulthood. Etiological accounts often point to childhood experiences as central to the development of personality disorders (Battle et al., 2004; J. G. Johnson et al., 1999; Laporte & Guttman, 1996). Evidence supports that personality disorders are more prevalent among those who have a history of child abuse (Pribor & Dinwiddie, 1992; Silverman, Reinherz, & Giaconia, 1996), suggesting that child abuse and neglect may play a role in their etiology.

Of the personality disorders, Borderline Personality Disorder (BPD) has been best investigated with regard to adverse child experiences (for a full review, see Zanarini, 2000). In general, research with BPD patients indicates higher reporting of childhood abuse (Herman, Perry, & van der Kolk, 1989; Ogata et al., 1990; Soloff, Lynch, & Kelly, 2002; Zanarini, Gunderson, Marino, Schwartz, & Frenkenburg, 1989; Zanarini et al., 1997) and child neglect (J. G. Johnson et al., 2000; Zanarini et al., 1989, 1997) than among patients with other personality disorders (Zanarini et al., 1989) or other Axis I psychiatric disorders (Ogata et al., 1990); however, these reports should have been interpreted with caution given that they are retrospective in nature.

The impact of the subtypes of maltreatment on the development of BPD is somewhat less clear. Childhood sexual abuse has been identified as a factor that discriminated patients with BPD from those with other personality disorders (Weaver & Clum, 1993); however, it has been noted that when childhood sexual abuse history has been identified among BPD patients, multiple forms of abuse and neglect are additionally present (Ogata et al., 1990; Zanarini et al., 1997, 2000).

The majority of research on maltreatment and personality disorders has compared BPD with an "other personality disorder" category, with very limited research into specific disorders (for a review, see Battle et al., 2004). Although there seems to be some empirical support that in addition to BPD, other personality disorder groups report a

high prevalence of childhood maltreatment histories (Gibb, Wheeler, et al., 2001), much of this evidence is again based on retrospective reports by psychiatric patients (B. Maughan & Rutter, 1997; Paris, 1997) and should be interpreted with caution (Widom & Morris, 1997; Widom & Shepard, 1996).

To address the limitation of retrospective data, a small body of longitudinal evidence is emerging in the field to support the hypothesis that childhood maltreatment increases risk for personality disorders in adulthood (R. E. Drake, Adler, & Vaillant, 1988; J. G. Johnson et al., 1999; Luntz & Widom, 1994). Such investigations have revealed that maltreatment is associated with the development of Antisocial Personality Disorder. Further, family instability and lack of parental affection and supervision during adolescence were associated with Dependent and Passive-Aggressive Personality Disorder among men. An additional community-based, longitudinal study showed that persons with documented child abuse were more than 4 times as likely as those who were not abused or neglected to be diagnosed with a personality disorder, after age, parental education, and parental psychiatric disorders were controlled statistically (J. G. Johnson et al., 1999). Specifically, physical abuse, sexual abuse, and neglect were each uniquely associated with elevated personality disorder symptom levels during early adulthood. Physical abuse was associated with Antisocial and Depressive Personality Disorder symptoms; sexual abuse was associated with elevated BPD symptoms; and neglect was associated with Antisocial, Avoidant, Borderline, Narcissistic, and Passive-Aggressive Personality Disorders. This investigation highlights the particular impact of neglect on personality disorder development (J. G. Johnson et al., 1999).

Finally, child maltreatment has been associated with maladaptive trajectories in the development of sexuality (i.e., Brown, Cohen, Chen, Smailes, & Johnson, 2004; Noll, Trickett, & Putnam, 2003). A recent prospective longitudinal study revealed that a history of two or more incidents of sexual abuse was associated with early puberty and early pregnancy, after gender, race, class, paternal absence, and mother's age at the birth of the study child were controlled statistically (Brown et al., 2004). In addition to heightened sexual activity and preoccupation, a subset of women with sexual abuse histories has been identified who exhibit sexual ambivalence or a heightened sexual preoccupation coupled with greater sexual aversion (Trickett & Putnam, 2003). In particular, pathological dissociation and biological father abuse may be associated with greater sexual aversion and sexual ambivalence. These investigations highlight the risk for premature sex-

ual behavior among maltreated adolescents; efforts to prevent teenage pregnancy should pay particular attention to sexually abused children as they enter puberty.

RESILIENT OUTCOMES

Consistent with a developmental psychopathology perspective, there is multifinality in developmental processes such that the manner in which the individual responds to and interacts with vulnerability and protective factors at each level of ecology allows for diversity of outcomes. Just as deviations from the average expectable environment potentiate some children toward the development of maladaptation, others evidence adaptation in the face of the same challenges. Thus, it is equally informative to understand the mechanisms that promote resilient functioning among maltreated children as it is to investigate developmental trajectories toward psychopathology (Masten, 1989). Maltreatment undisputedly represents an extremely adverse and stressful experience, yet not all maltreated children demonstrate maladaptive outcomes. Thus, the study of resilience among maltreated children seeks to understand the dynamic processes that influence how the various aspects of children's ecologies eventuate in multiplicity in child developmental outcome, adaptive or maladaptive.

Resilience has been conceptualized as the individual's capacity for adapting successfully and functioning competently, despite experiencing chronic stress or adversity following exposure to prolonged or severe trauma (Masten & Coatsworth, 1998). It is important that the construct of resilience be conceptualized as a dynamic process, not a static or trait-like condition (Cicchetti & Schneider-Rosen, 1986; Egeland, Carlson, & Sroufe, 1993; Luthar, Cicchetti, & Becker, 2000), so that resilience research may elucidate the mechanisms through which individuals are able to initiate or maintain their self-righting tendencies when confronted with adversity (cf. Cicchetti & Rizley, 1981; Waddington, 1957). Understanding resilience will contribute to our understanding of how ontogenic processes play a critical role in determining whether adaptation or maladaptation will manifest at each stage of development (Cicchetti & Tucker, 1994).

Initial resilience research sought to identify correlates of resilient outcomes in maltreated children; however, given the nature of resilience as a dynamic process, longitudinal research most adequately can address its development. Unfortunately, there are few longitudinal studies that track subsequent adaptive functioning among maltreated children. The extant longitudinal investigations of resilient functioning among young maltreated children through age

6 have highlighted both the dynamic nature of resilient processes and the poor developmental outcomes associated with maltreatment (Egeland & Farber, 1987; E. C. Herrenkohl, Herrenkohl, & Egolf, 1994). For example, Egeland and Farber found that not a single maltreated child included in their study consistently functioned competently across each age period assessed, in which competence was defined as successful resolution of a stage-salient issue at each level of development. Moreover, Herrenkohl, Herrenkohl, and Egolf found that fewer than 15% of children who had been maltreated prior to age 6 were identified as resilient, and when contacted in adolescence, nearly 50% of these previously resilient maltreated children were no longer demonstrating resilient functioning.

Among the protective factors that have been identified to promote resilient functioning are average or above-average intellectual performance, absence of physical abuse, the presence of at least one stable caregiver, and positive parental expectations regarding their children's academic performance (E. C. Herrenkohl et al., 1994; Masten et al., 1999). Highlighting the role of individual child characteristics in the development of adaptation, children's academic engagement, social competencies, and ego resiliency have all been positively associated with adaptation to school (Shonk & Cicchetti, 2001). Personality characteristics such as internal locus of control for good events and higher self-esteem are further examples of individual characteristics that serve a protective function for children, mitigating the risk for maladaptive outcomes (Moran & Eckenrode, 1992).

In perhaps the most comprehensive assessments of resilient functioning among maltreated school-age children, Cicchetti and Rogosch (1997) improved on their prior cross-sectional investigation of predictors and correlates of resilience (Cicchetti, Rogosch, Lynch, & Holt, 1993) by assessing the longitudinal adaptation of over 200 children over a 3-year period. For both studies, resilient adaptation among multiple areas of functioning was evaluated within a heterogeneous sample of economically disadvantaged maltreated children and nonmaltreated comparison children. In their earlier investigation, maltreated children evinced lower overall competence across multiple indices of functioning than the nonmaltreated children. Moreover, maltreated children were rated as more withdrawn, with significantly greater levels of internalizing symptomatology, more disruptive, and more aggressive. Nonetheless, ego resiliency, ego overcontrol, and self-esteem emerged as predictors of resilient adaptation for maltreated children. In contrast, only ego resiliency and positive self-esteem were associated with resilient functioning among nonmaltreated children (Cicchetti, Rogosch, et al., 1993).

Similarly, the longitudinal investigation revealed that a higher percentage of nonmaltreated children evidenced resilient functioning than did maltreated children; furthermore, a high percentage of maltreated children were functioning in the low-adaptive range (Cicchetti & Rogosch, 1997). Notably, different predictors of resilience emerged for the maltreated and nonmaltreated children such that for maltreated children, positive self-esteem, ego resilience, and ego overcontrol predicted resilient functioning, whereas relationship features were more influential for nonmaltreated children. These findings suggest that perhaps, in the face of unfulfilling relationships, the maltreated children who demonstrate resilient functioning have developed an adaptive coping mechanism toward less reliance on relatedness in their everyday functioning. Considering that personality resources and self-confidence were major predictors of resilient adaptation in maltreated children, Cicchetti and Rogosch posit that interventions that focus on the enhancement of self system processes such as autonomy, mastery, and self-determination may be effective (Ryan et al., 1995).

Highlighting additional pathways to resilient functioning, Flores et al. (2005) conducted a similar assessment of multiple domains of functioning with a sample of high-risk Latino maltreated and nonmaltreated children. Although prior research had identified predictors of resilient adaptation in maltreated children, there was a lack of knowledge regarding whether these same factors would be applicable to Latino children. Considering evidence that relationships are very highly valued in Latino cultures (Harrison, Wilson, Pine, Chan, & Buriel, 1990), Flores and colleagues sought to determine whether relationship features would serve as predictors of resilient adaptation for both maltreated and nonmaltreated Latino children. Consistent with prior investigations of resilience, which have been composed of mainly African American and Caucasian American children (Cicchetti & Rogosch, 1997; Cicchetti et al., 1993; McGloin & Widom, 2001), maltreated Latino children demonstrated a lower level of resilient functioning than did equally disadvantaged nonmaltreated Latino children. For both maltreated and nonmaltreated Latino children, higher ego resiliency and moderate ego overcontrol were associated with higher resilient functioning. Thus, in contrast to prior investigations (Cicchetti & Rogosch, 1997), the effects of ego resiliency and ego overcontrol did not differentially predict resilience for maltreated and nonmaltreated Latino children. In accord with previous findings, however, the predictive impact of relationship variables on resilience was more significant for nonmaltreated than maltreated Latino children (Flores et al.,

2005). These findings suggest that among Latino children, personal strengths such as ego resiliency and ego overcontrol may be more essential than relationship features in determining a pathway to resilient adaptation.

Taken together, it seems that self-reliance and self-confidence, in concert with interpersonal reserve, may bode well for the development of resilient adaptation in maltreated children. This is congruent with findings among highly stressed, disadvantaged youngsters, such that positive future expectations for the self are a predictor of resilient functioning (Wyman, Cowen, Work, & Kerley, 1993). Research on resilience attests to the critical role that children play in actively constructing their outcomes and in influencing their ultimate adaptation through mechanisms such as reliance on the self, confidence in the self, and interpersonal reserve.

Currently, the field of resilience is now headed toward an incorporation of neurobiological and physiological factors (Curtis & Cicchetti, 2003) in elucidating the biological mechanisms of ontogenic development and self-striving processes. According to a transactional-organizational perspective, which conceptualizes resilience as a dynamic process akin to all other developmental processes, resilience is influenced by neural and psychological self-organization as well as by transactions between the ecological context and the developing organism. Neural plasticity, in particular, may be well applied to the concept of resilience (Cicchetti, 2002, 2003; Curtis & Nelson, 2003), and may provide a neurobiological account for the ability of an individual to recover after exposure to trauma or adversity. Alternatively, it is possible that certain genetic predispositions may account for the variation of the extent to which individuals are impacted by environmental influences. Research from the fields of emotion regulation, psychophysiology, neuroendocrinology, and genetics are just beginning to elucidate how neurobiological and physiological mechanisms contribute to the self-striving tendencies of ontogenic development and through reciprocal interactions with varying levels of ecology exert an influence on developmental outcomes, both adaptive and maladaptive (Caspi et al., 2002; Cicchetti & Rogosch, 1997; Curtis & Cicchetti, 2003; McEwen, 1998).

NEUROBIOLOGICAL ONTOGENIC DEVELOPMENT AND GENE EXPRESSION: THE DEVELOPING BRAIN AS A SELF-ORGANIZING DYNAMIC SYSTEM

Scientific investigations on child maltreatment have focused predominantly on psychological processes and out-

comes. In recent years, the examination of the neurobiological correlates and sequelae of child abuse and neglect have now begun to receive more attention from researchers. Such work holds great promise for elucidating the mechanisms underlying maladaptive development in maltreated children and for examining the impact that negative social experiences exert on brain structure and function, as well as on gene expression. As research on the effects of child maltreatment on neurobiological structure and function and on gene expression continues to burgeon, it is conceivable that the examination of the multifaceted neurobiological systems affected by child maltreatment, as well as the investigation of the impact that maltreatment experiences have on gene expression, will provide insight into some of the mediators and moderators linking child maltreatment with socioemotional and cognitive outcomes.

Although brain development is guided and controlled to some degree by genetic information, a not insignificant portion of postnatal brain structuration, neural patterning, and organization are thought to occur through interactions and transactions of the individual with the environment (J. Black, Jones, Nelson, & Greenough, 1998; M. H. Johnson, 1998). Thus, each individual may traverse a potentially unique and partly self-determined developmental pathway of brain building that we believe may have important consequences for the development of normal, abnormal, and resilient adaptation (J. Black et al., 1998; Cicchetti & Tucker, 1994; Curtis & Cicchetti, 2003).

In self-organizing brain development (Cicchetti & Tucker, 1994; Courchesne, Townsend, & Chase, 1995), some regions of the brain serve to stabilize and organize information for other areas, whereas other regions utilize experience to fine-tune their anatomy for optimal function. In this manner, individuals can use the interaction of genetic constraints and environmental information to self-organize their highly complex neural systems. Synaptogenesis appears to be generated in response to events that provide information to be encoded in the nervous system (Courchesne, Chisum, & Townsend, 1994). This experience-dependent synapse formation involves the brain's adaptation to information that is unique to the individual (Greenough, Black, & Wallace, 1987). Because all individuals encounter distinctive environments, each brain is modified in a singular fashion. Experience-dependent synaptogenesis is localized to the brain regions involved in processing information arising from the event experienced by the individual. Unlike the case with experience-expectant processes, experience-dependent processes do not take place within a stringent temporal interval because the timing or nature of experience that the individual engages or

chooses cannot be entirely envisioned (Bruer, 1999). An important central mechanism for experience-dependent development is the formation of new neural connections, in contrast to the overproduction and pruning back of synapses often associated with experience-expectant processes (Greenough et al., 1987; Huttenlocher, 1994).

For example, children who develop in a resilient fashion despite having experienced significant adversity play an active role in constructing, seeking, and receiving the experiences that are developmentally appropriate for them (J. Black et al., 1998; Cicchetti & Tucker, 1994). Through utilizing experience-dependent processes, children who function resiliently likely modify and/or protect their brain anatomy to ensure an adaptive developmental outcome (Curtis & Cicchetti, 2003). At one level, different areas of the brain may attempt to compensate, and, at another, the organism may seek out new experiences in areas where it has strength (J. Black et al., 1998). Because experience-dependent plasticity is a central feature of the mammalian brain (M. Johnson, 1999), neither early brain anomalies nor aberrant experiences should be considered as determining the ultimate fate of the organism (Cicchetti & Tucker, 1994).

Furthermore, because the mechanisms of neural plasticity cause the brain's anatomical differentiation to be dependent on stimulation from the environment, it is now clear that the cytoarchitecture of the cerebral cortex is shaped by input from the social environment. Cortical development and organization should not be viewed as passive processes that depend exclusively on genetic and environmental input. Development, both psychological and biological, is more than nature-nurture interaction. Thus, corticogenesis should be conceived as processes of self-organization guided by self-regulatory mechanisms (Cicchetti & Tucker, 1994).

Children endowed with normal brains may encounter a number of experiences, including child maltreatment, extreme poverty, and community and domestic violence, that can not only exert a negative impact on brain structure, function, and organization, but also contribute to distorting these children's experiences of the world (Cicchetti, 2002; Pollak, Cicchetti, & Klorman, 1998). Perturbations that occur during brain development can potentiate a cascade of maturational and structural changes that eventuate in the neural system proceeding along a trajectory that deviates from that generally taken in normal neurobiological development (Courchesne et al., 1994; Nowakowski & Hayes, 1999). Early stresses, either physiological or emotional, may condition young neural networks to produce cascading

effects through later development, possibly constraining the child's flexibility to adapt to challenging situations with new strategies rather than with old conceptual and behavioral prototypes. Thus, early psychological trauma such as that experienced by maltreated children may eventuate not only in emotional sensitization (A. Maughan & Cicchetti, 2002), but also in pathological sensitization of neurophysiological reactivity (Cicchetti & Tucker, 1994; Pollak et al., 1998). Such early developmental abnormalities may lead to the development of aberrant neural circuitry and often compound themselves into relatively enduring forms of psychopathology (Cicchetti & Cannon, 1999; Nowakowski & Hayes, 1999).

Children may be especially vulnerable to the effects of pathological experiences during periods of rapid creation or modification of neuronal connections (J. Black et al., 1998). Pathological experience may become part of a vicious cycle, as the pathology induced in brain structure may distort the child's experience, with subsequent alterations in cognitive or social interactions causing additional pathological experience and added brain pathology (Cicchetti & Tucker, 1994; Pollak et al., 1998). Children who incorporate pathological experience during ongoing experience-expectant and experience-dependent processes may add neuropathological connections to their developing brains instead of functional neuronal connections (J. Black et al., 1998).

The Impact of Child Maltreatment on Neurobiological Processes

Adverse life experiences, exemplified by the experience of child maltreatment, are thought to affect neurobiological and psychological processes. Physiological and behavioral responses to maltreatment are expected to be interrelated and to contribute to children's making choices and responding to experiences in ways that generally produce pathological development. Because maltreated children experience the extremes of "caretaking casualty" (Sameroff & Chandler, 1975), they provide one of the clearest opportunities for scientists to discover the multiple ways in which social and psychological stressors can affect biological systems. Numerous interconnected neurobiological systems are affected by the various stressors associated with child maltreatment (Cicchetti, 2002; DeBellis, 2001). Moreover, each of these neurobiological systems influences and is influenced by multiple domains of psychological and biological development. Furthermore, in keeping with the principle of multifinality, the neurobiological development

of maltreated children is not affected in the same way in all individuals. Not all maltreated children exhibit anomalies in their brain structure or functioning.

Neurobiological Structure: Neuroimaging

Magnetic resonance imaging (MRI) technology provides a noninvasive and safe methodology for examining brain morphology, physiology, and function in individuals who have experienced child maltreatment. Several MRI investigations have found reduced hippocampal volume in victims of psychological trauma with PTSD. Bremner, Krystal, Southwick, and Charney (1995) discovered that male combat veterans with PTSD evidenced decreased MRI-derived right-side hippocampal volume and that aspects of the memory deficits exhibited by the combat veterans with PTSD correlated with hippocampal volume. Gurvits and colleagues (1996) replicated the finding of reduced hippocampal volume in an MRI study of male combat veterans. In contrast to Bremner et al., Gurvits et al. found hippocampal reduction bilaterally. In a heterogeneous sample of men and women who experienced abuse in their childhood, Bremner et al. (1997) discovered a reduction in left-side hippocampal volume compared to nonabused comparisons. Relatedly, M. B. Stein, Yehuda, Koverola, and Hanna (1997) found that women who reported being sexually abused in childhood showed a reduced left-side hippocampal volume compared to nonsexually traumatized women. Vythilingam and colleagues (2002) conducted an MRI investigation of a group of adult females who had a current diagnosis of Major Depressive Disorder (MDD). Two-thirds of the women with MDD had a history of child physical or sexual abuse; the other depressed women had no abuse histories. The two groups of women with MDD were compared to a group of healthy women. Depressed women who had experienced abuse in their childhood have a significantly smaller hippocampal volume than the nonabused depressed women and the women in the healthy comparison group.

In a more recent investigation, Bremner and colleagues (2003) conducted an MRI and a positron emission tomography (PET) study with a group of women who experienced sexual abuse and PTSD in their childhood, another group of women who had experienced sexual abuse but who did not have PTSD, and a comparison group of women without sexual abuse or PTSD. Utilizing MRI, Bremner et al. found that women who had been sexually abused had significantly smaller hippocampi than either women who had been sexually abused without PTSD or women who were

without sexual abuse histories or PTSD. Additionally, the women with sexual abuse and PTSD showed a failure of left hippocampal activation during a verbal memory task that was measured by PET. This finding remained significant after adjusting for hippocampal atrophy.

In a functional magnetic resonance imaging (fMRI) study, Anderson, Teicher, Polcari, and Renshaw (2002) performed steady-state fMRI (T2 relaxometry) to assess resting blood flow in the cerebellar vermis. Adults who had been sexually abused in childhood manifested higher T2 relaxation times (T2-RT) than controls. Elevated T2-RT measures have been shown to be associated with decreased blood volume and neuronal activity. Anderson et al. interpreted the elevated T2-RT found in the cerebellar vermis of these adults who had experienced sexual abuse as indicative of a possible pathway from early abuse → functional deficits in the cerebellar vermis → reduced neuronal activity → decreased blood volume.

Over the course of the past decade, neuroimaging studies have been conducted with maltreated children and adolescents. DeBellis, Keshavan, and colleagues (1999) conducted an in-depth whole-brain volumetric analysis of a group of hospitalized maltreated children and adolescents with PTSD and a group of medically and psychiatrically well nonmaltreated comparison subjects. In keeping with the literature on child maltreatment, most of the participants had experienced multiple types of maltreatment. Moreover, in addition to PTSD, most of the children and adolescents who were maltreated had comorbid mental disorders. These included Major Depressive Disorder, Dysthymia, Oppositional Defiant Disorder, and Attention-Deficit/Hyperactivity Disorder. Of particular importance, given that the hippocampus is susceptible to the harmful effects of chronic alcohol abuse, substance and alcohol abuse were rare in the DeBellis, Keshavan, et al. study.

In contrast to the findings of the investigations of adults who had childhood histories of abuse reviewed above, DeBellis, Keshavan, et al. (1999) did not find a decrease in hippocampal volume in the group of maltreated children and adolescents with PTSD. Moreover, DeBellis, Hall, Boring, Frustaci, and Moritz (2001) examined hippocampal volumes longitudinally to determine if a history of childhood maltreatment and PTSD alter the growth of the hippocampus during puberty. DeBellis and colleagues (2001) utilized MRI to scan the brains of maltreated children with PTSD and healthy nonmaltreated comparison children matched on SES on two occasions, once when they were prepubertal and then again 2 to 3 years later during the later stages of puberty (i.e., Tanner Stages IV

and V). MRI was used to measure the temporal lobes, amygdala, and hippocampal volumes of the two groups of children. There were no differences in temporal lobe, amygdala, or hippocampal volume between the group of maltreated children with PTSD and the matched group of nonmaltreated children, either at baseline or across longitudinal follow-up.

These apparent discrepant findings may be a function of the increase in volume that normatively occurs in neurobiological development during adolescence (Spear, 2000, 2003). Specifically, subcortical gray matter structures that include the hippocampus continue to develop, and these normative adolescent increases (i.e., the normal processes of brain development) may mask any effects that maltreatment and PTSD exert on the developing limbic system (e.g., amygdala, hippocampus). It is conceivable that the stress-induced hippocampal damage may not become apparent until postpubertal development has been initiated. Alternatively, because the maltreated children with PTSD in the DeBellis et al. (2001) sample were in ongoing individual or group treatment, it may be the case that these interventions may have eventuated in increases in hippocampal neurogenesis, thereby contributing to the lack of statistically significant differences.

After controlling for intracranial volume and SES, DeBellis and colleagues (DeBellis, Keshavan, et al., 1999) discovered a number of other MRI-based brain structural anomalies in their sample of maltreated children and adolescents with PTSD. These included smaller intracranial volumes, cerebral volumes, and midsagittal corpus callosum areas and larger lateral ventricles than in the group of nonmaltreated comparison children and adolescents. In addition, DeBellis, Keshavan, et al. found a positive correlation of intracranial volumes with age of onset of PTSD trauma and a negative correlation with the duration of maltreatment that led to a PTSD diagnosis, suggesting that there may be sensitive periods and dose effects for stress-related alterations in brain development. Furthermore, DeBellis, Keshavan, et al. interpret their finding that enlarged lateral ventricles in maltreated children and adolescents were correlated positively with the duration of the maltreatment experienced as suggesting that there may have been neuronal loss associated with severe stress (cf. Sapolsky, 1992).

In another investigation, DeBellis, Keshavan, Spencer, and Hall (2000) utilized magnetic resonance spectroscopy (MRS), a safe and novel neuroimaging methodology, to investigate the *in vivo* neurochemistry of neurobiological alterations in the brains of living children. DeBellis and colleagues used MRS to measure the relative concentration

of N-acetyl aspartate (NAA) and creatine in the anterior cingulate cortex of a small group ($n = 11$) of maltreated children and adolescents who also had PTSD and a healthy nonmaltreated comparison group ($n = 11$) matched on SES. NAA is considered to be a marker of neural integrity; moreover, decreased concentrations of NAA are associated with increased metabolism and loss of neurons (Prichard, 1996). DeBellis et al. found that maltreated children and adolescents with PTSD had lower NAA-to-creatine ratios that are suggestive of neuronal loss in the anterior cingulate region of the medial prefrontal cortex compared to the nonmaltreated SES-matched comparisons. The reduction of NAA to creatine, in addition to DeBellis, Keshavan, et al.'s (1999) finding of enlargement in the lateral ventricles, buttress the hypothesis that maltreatment in childhood may alter the development of cortical neurons.

Teicher and colleagues (2004) investigated the corpus callosum in children who had been abused or neglected to ascertain whether there were structural abnormalities in its regional anatomy. The corpus callosum connects the left and right hemispheres and is the major myelinated tract in the brain. Regional corpus callosum area was measured by MRI in three groups of children: abused and neglected children, children admitted for psychiatric evaluation, and healthy controls. Teicher et al. found that the total area of the corpus callosum of the children who had experienced abuse and neglect was smaller than that of the children evaluated for psychiatric problems and the healthy controls. The latter two groups of children did not differ from each other. Child neglect was associated with a 15% to 18% reduction in corpus callosum regions; in contrast, reduced corpus callosum size in girls was most strongly associated with sexual abuse. These findings are congruent with our earlier assertion that negative early experiences can adversely affect neurobiological development.

In summary, the neuroimaging studies reviewed attest to the harmful impact that child maltreatment can exert on brain development and function. As important, not all maltreated children evidence the same neurobiological structural and functional anomalies. Moreover, some maltreated children appear to have normal neurobiological development and function despite experiencing great adversity. Many important questions remain to be answered (see conclusion and future directions section).

Neurobiological Functioning

Startle expression in humans and in laboratory animals is affected by emotional factors, a connection that may be

grounded in the evolutionary value of startle for immediate protection. The disturbances of anxiety and traumatization that have been found in childhood maltreatment (Cicchetti & Lynch, 1995) and the sensitivity of the startle reflex to these conditions suggested the utility of examining startle patterns in maltreated children for developing objective physiological markers of the severity of traumatization. Accordingly, Klorman, Cicchetti, Thatcher, and Ison (2003) investigated acoustic startle in maltreated and nonmaltreated comparison children to a range of auditory intensities to describe any abnormalities in response magnitude, onset latency, and habituation. Additionally, startle differences among subtypes of maltreated children were examined.

The acoustic startle reflex is an obligatory response to a sudden and unexpected stimulus that is marked by the cessation of ongoing behaviors and by a particular series of protective behaviors (Davis, 1984). The eyeblink is the most sensitive and consistent startle response across individuals, and this is the response that is most often measured in studies of this reflex. The startle eyeblink in humans is measured by electromyographic activity detected by electrodes overlying the obicularis oculi muscle, located below each eye.

Klorman et al. (2003) examined acoustic startle to 24 randomly ordered 50-ms. binaural white noise burst probes of 70, 85, 100, and 115 dB while children were watching silent cartoons. The participants were maltreated and nonmaltreated children matched for age, sex, and socioeconomic status (see Klorman et al., 2003). Maltreated boys' startle blinks had smaller amplitude and slower onset latency and were less affected by increasing probe loudness than were those of comparison boys. Among maltreatment subtypes, this pattern was most salient for physically abused boys. Unfortunately, there were not enough physically abused girls to detect any potential differences from comparison children. The results for maltreated boys also are consistent with those of Ornitz and Pynoos (1989) for diminished startle responses among children with PTSD. These investigators suggested that startle diminution in traumatized children may reflect cortically mediated attentional dysfunction that affected brain stem mechanisms for startle responses. Thus, it is conceivable that the effects of social experiences, such as child abuse and neglect, on brain microstructure and biochemistry may be either pathological or adaptive.

The findings obtained with the physically abused boys are consistent with those of Cicchetti and Rogosch (2001a). These investigators found that physically abused children

displayed a suppression of cortisol and significantly less diurnal variation in hypothalamic-pituitary-adrenal (HPA) functioning than did other subtypes of maltreated children. Although startle responsiveness and cortisol regulation are linked to separate, but interconnected, neurobiological systems, in both investigations physically abused children exhibited diminished responsiveness. Physically abused children are often exposed to threat and danger, and their smaller responses to startle and their suppression of cortisol may reflect allostatic load, the cumulative long-term effect of physiologic responses to stress (Evans, 2004; McEwen, 2000, 2004; McEwen & Stellar, 1993). Repetitive social challenges in a child's environment, such as that engendered by child abuse and neglect, can cause disruptions in basic homeostatic and regulatory processes that are essential to the maintenance of optimal physical and mental health (Repetti, Taylor, & Seeman, 2002).

Neuroendocrine Functioning

Stress has been conceptualized as a perceived threat to an organism's homeostasis and as a situation that causes increases in autonomic nervous system activity or hormone secretion (Cicchetti & Walker, 2001). An overt insult or homeostatic mechanism initiates a stress response; however, as the term "perceived stress" connotes, psychological factors can initiate a stress response on their own. The confluence of a number of factors, including genetic makeup, prior experiences, and developmental history, either sensitize or protect the organism from subsequent stressful challenges (McEwen, 1998). In addition, more long-term stress responsiveness is characterized by interindividual variability and is related, in part, to experiential influences on gene expression (Meaney et al., 1996). In sum, then, there are multiple converging pathways—including not only the neural circuits that are activated by physical, psychological, and immunological stressors, but also the influence of genetics, early experience, and ongoing life events—that determine the neural response to different stressors (Sapolsky, 1994).

Stressful or threatening experiences such as child abuse and neglect create adaptational challenges, and the HPA axis is one of the physiological systems that has evolved in mammals to help direct and sustain cognitive, emotional, behavioral, and metabolic activity in response to threat. Basal activity of this neuroendocrine system follows a circadian rhythm, with high levels around the time of awakening, declining to low levels around the onset of sleep (Kirschbaum & Hellhammer, 1989). Basal levels of cortisol

are necessary for normal brain growth and for the support of the metabolic activity necessary to sustain general functioning (McEwen, 1998).

Incidents of child maltreatment, such as sexual, physical, and emotional abuse, as well as neglect, may engender massive stress in vulnerable children. Acute threat and emotional distress, as is found in instances of child maltreatment, may activate the locus coeruleus, the major noradrenergic-containing nucleus in the brain, and the sympathetic nervous system (SNS), eventuating in the biological changes accompanying the "fight or flight" reaction. Stressful experiences such as child maltreatment may potentiate the increased production of corticotropin-releasing hormone (CRH) in the central amygdala and in the hypothalamus. CRH from the amygdala causes increased SNS activity, thereby promoting heightened behavioral and attentional arousal (Kaufman & Charney, 2001; Schulkin, McEwen, & Gold, 1994). CRH from the paraventricular nucleus of the hypothalamus, in concert with other hormones such as vasopressin, stimulate the production of adrenocorticotrophic hormone (ACTH) in the anterior pituitary. The ACTH that is secreted into circulation selectively stimulates cells of the adrenal cortex to produce and release cortisol, a potent steroid hormone that impacts nearly all organs and tissues of the body (Lopez, Akil, & Watson, 1999; Vazquez, 1998). Cortisol, through negative feedback inhibition on the hypothalamus, pituitary, and additional brain structures, such as the hippocampus, suppresses the HPA axis, thereby bringing about restoration of basal levels of cortisol. Among its many influences, cortisol affects the central neural processes that are implicated in cognition, memory, and emotion.

The capacity to elevate cortisol in response to acute trauma is critical for survival. Brief elevations in corticosteroids following acute stressors appear to enhance the individual's ability to manage stressful experience competently, both physiologically and behaviorally. However, chronic hyperactivity of the HPA axis may eventuate in the accelerated loss or metabolism of hippocampal neurons, the inhibition of neurogenesis, lags in the development of myelination, abnormalities in synaptic pruning, and impaired affective and cognitive ability (Gould, Tanapat, McEwen, Flugge, & Fuchs, 1998; Sapolsky, 1992; Todd, Swarzenski, Rossi, & Visconti, 1995). Moreover, the elimination of glucocorticoids also can damage neurons (Gunnar & Vazquez, 2001; Heim, Ehler, & Hellhammer, 2000). Specifically, there is a phenomenon known as hypocortisolism in which individuals who are experiencing chronic stressors such as ongoing maltreatment may manifest reduced adrenocortical secretion, reduced adrenocortical re-

activity, or enhanced negative feedback inhibition of the HPA axis (Gunnar & Vazquez, 2001; Heim et al., 2000). Consequently, it is in an organism's best interests to avoid both chronic glucocorticoid hypersecretion and hyposecretion (Sapolsky, 1996).

A number of investigations have been conducted that indicate atypical physiological processes in maltreated children. Noradrenergic, dopaminergic, serotonergic, and glucocorticoid systems, which are activated by stress, all are affected by child maltreatment (Kaufman & Charney, 2001). For example, abnormal noradrenergic activity, as evidenced by lower urinary norepinephrine (NE), has been found in children who have been abused and neglected (Rogeness, 1991). In addition, neglected children have been shown to have lower levels of dopamine (DA)-beta-hydroxylase (DBH), an enzyme involved in the synthesis of NE, than do abused children or normal controls (Rogeness & McClure, 1996). Neglected children also were found to have lower systolic and diastolic blood pressure, both of which are functions mediated by the NE system. These findings from Rogeness's laboratory suggest that the experience of child neglect modifies the genetic expression of DBH activity and the NE system.

Sexually abused girls have been shown to excrete significantly greater amounts of the DA metabolite homovanillic acid (DeBellis, Leffer, Trickett, & Putnam, 1994). Augmented mean morning serial plasma cortisol levels have been found in sexually abused girls, implicating altered glucocorticoid functioning in the HPA axis (Putnam, Trickett, Helmers, Dorn, & Everett, 1991). Relatedly, the attenuated plasma ACTH response to the ovine CRH stimulation test in sexually abused girls further suggests a dysregulatory disorder of the HPA axis, associated with hyporesponsiveness of the pituitary to exogenous CRH and normal overall cortisol secretion to CRH challenge (DeBellis et al., 1993). Sexually abused children with PTSD have been found to excrete significantly greater concentrations of baseline NE and DA in comparison to nonabused anxious and normal healthy controls (DeBellis, Baum, et al., 1999). These findings suggest that the combination of sexual abuse experiences and PTSD is associated with enduring alterations of biological stress systems.

In two separate studies, it has been found that maltreated school-age children with depressive disorder fail to manifest the expected diurnal decrease in cortisol secretion from morning to afternoon (J. Hart, Gunnar, & Cicchetti, 1996; Kaufman, 1991). In a subsequent investigation, it was shown that, when compared to depressed, abused, and normal nonmaltreated comparison children, maltreated prepubertal depressed children who were resid-

ing under conditions of chronic ongoing adversity displayed an increased human CRH-induced ACTH response but normal cortisol secretion. In contrast, depressed children with prior abuse histories but who were currently living in a stable environment did not differ in their HPA functioning from the depressed abused or the normal non-maltreated comparison children (Kaufman et al., 1997). The finding that present microsystem supports can serve as a protective factor against HPA axis dysregulation highlights the malleability of the neuroendocrine system. DeBellis, Baum, et al. (1999) examined the relationship between psychiatric symptomatology and urinary free cortisol (UFC) and catecholamine (epinephrine [EPI], NE, and DA) excretion in prepubertal maltreated children with PTSD. Two groups of children served as the comparisons: nontraumatized children with Overanxious Disorder (OAD) and healthy nontraumatized children without any psychiatric disorder. DeBellis, Baum, and colleagues discovered that maltreated children with PTSD excreted significantly greater concentrations of urinary DA and NE over a 24-hour period than did the OAD and healthy comparison children. Moreover, maltreated children with PTSD excreted significantly greater concentrations of urinary EPI than did the children with OAD. Furthermore, childhood PTSD was related to greater comorbid psychopathology, including depressive and dissociative symptoms and increased incidents of lifetime suicide ideation and attempts. The findings of the DeBellis, Baum, et al. investigation provide further evidence that maltreatment experiences, in combination with PTSD, are associated with alterations in biological stress systems.

Cicchetti and Rogosch (2001a, 2001b) have conducted two investigations of cortisol regulation in school-age maltreated and nonmaltreated children. These studies were implemented in the context of a research summer day camp program. Because attendance at this summer camp was a novel experience, these youngsters did not know what to expect from the adult camp counselors (who were unfamiliar to the children). Moreover, children in the camp were unfamiliar with each other. Thus, the camp context constituted a social challenge for the children in attendance, making it a context appropriate to investigate the impact of stress on neuroendocrine function.

Saliva samples were collected twice daily through the week children participated in camp. One advantage of the naturalistic camp setting was that it permitted saliva to be collected from the children during uniform time periods (i.e., at 9 A.M., as soon as the children arrived at camp in a bus, and at 4 P.M., shortly before they were bused home at the end of the day). Cortisol assays were conducted

without awareness of the maltreatment status of participating children.

In the first investigation, Cicchetti and Rogosch (2001a) found substantial elevations in the morning cortisol levels of maltreated children who had been both sexually abused and physically abused, as well as neglected or emotionally maltreated. Additionally, many of the children in this multiple abuse group also exhibited elevated cortisol concentrations in both the morning and afternoon assayed saliva collections.

Unlike what was obtained in the multiple abuse group of children, a subgroup of youngsters who had experienced physical abuse evidenced a trend toward lower morning cortisol concentrations relative to the nonmaltreated children. Moreover, this physically abused subgroup of children displayed a significantly smaller decrease in cortisol levels from morning sample concentrations to afternoon sample concentrations. This pattern of cortisol production suggests relatively less diurnal variation for the physically abused group of children.

Finally, no differences in patterns of cortisol regulation were obtained between the neglected and the emotionally maltreated groups of children and the comparison group of nonmaltreated children.

The divergent patterns of cortisol regulation for the varying subgroup configurations of maltreated children suggest that it is highly unlikely that the brains of all children are uniformly affected by the experience of maltreatment. Not all maltreated children exhibited HPA axis functioning dysregulation. Only those maltreated children who experienced sexual and physical abuse in combination with neglect or emotional maltreatment displayed patterns akin to hypercortisolism. This group of children may be at extremely high risk for developing compromised neurobiological structure and function. Children in the physically abused subgroup manifested reduced adrenocortical reactivity, or enhanced negative feedback of the HPA axis, a pattern suggestive of hypocortisolism and that also may cause long-term neurobiological sequelae.

The children in the multiple abuse group had experienced chronic maltreatment across a range of developmental periods. This multifaceted assault on cognitive, social, emotional, and biological systems most likely contributes to these children's expectations of continued adversity. The pervasive negative experiences that these multiply abused children have encountered contribute significantly to these children's construction of their worlds as marked by fear and a hypersensitivity to future maltreatment.

In the second investigation, Cicchetti and Rogosch (2001b) examined the relations between neuroendocrine

functioning and psychopathology in maltreated school-age children. The study also was implemented in a summer research day camp context. Once again, salivary samples were collected at the beginning and the end of the camp day. All samples were subsequently assayed for cortisol without knowledge of the children's maltreatment status.

Cicchetti and Rogosch (2001b) utilized the clinical cut points from the Teacher Report Form (TRF) and the Child Depression Inventory (CDI; Kovacs, 1985) to categorize maltreated and nonmaltreated children into clinical case groups. At the conclusion of the week, camp counselors completed the TRF and the children completed the CDI. Counselors were unaware of the children's maltreatment status. Children were identified as exhibiting clinical-level internalizing-only psychopathology if they had clinical-level scores on the TRF internalizing scale and/or the CDI and did not exhibit clinical-level problems on the TRF externalizing scale.

Maltreated children with clinical-level internalizing problems exhibited increased morning and across-the-day average levels of cortisol compared with the other groups of maltreated and nonmaltreated children (Cicchetti & Rogosch, 2001b). These results suggest that the presence of maltreatment moderated the impact of clinical-level internalizing problems. Furthermore, maltreated children with clinical-level internalizing problems displayed higher afternoon cortisol than did nonmaltreated children with clinical-level internalizing problems.

The increased levels of cortisol found in the maltreated children with clinical levels of internalizing problems differ from those typically obtained in samples of children and adolescents with MDD. The latter groups rarely exhibit the increase in cortisol that is characteristic of a regulatory dysfunction of the HPA axis (Dahl & Ryan, 1996). Consistent with the scientific literature on childhood depression, the nonmaltreated children with case-level internalizing problems in our study did not display increased levels of cortisol and an HPA axis dysregulation. Thus, it appears that the experience of maltreatment intensifies the usual effects of depressive disorder in childhood on neuroendocrine functioning. Accordingly, maltreated children with significant internalizing psychopathology may be at risk for developing the neurobiological anomalies associated with hypercortisolism.

Interestingly, the HPA axis abnormalities of maltreated children with clinical levels of internalizing problems bear striking similarity to those obtained with maltreated children with PTSD and MDD reported by DeBellis, Baum, and colleagues (1999) and with depressed adults who were sexually or physically abused during their childhood (Heim

& Nemeroff, 2001; Heim, Newport, Bonsall, Miler, & Nemeroff, 2001; Lemieux & Coe, 1995).

Notably, not all maltreated children with clinical levels of internalizing psychopathology displayed the same pattern of cortisol regulation. This finding provides further evidence that maltreatment experiences do not uniformly affect neurobiological functioning in all children.

Finally, a number of retrospective investigations of neuroendocrine functioning in adults who had been exposed to maltreatment in childhood have been conducted. Although a detailed review of these studies is beyond the scope of this chapter, these studies cohere in concluding that maltreatment in childhood renders individuals more vulnerable to neuroendocrine dysregulation (assessed through urinary assessments of cortisol concentration and biological challenge tests) and psychopathology in adulthood (Heim et al., 2000, 2001, 2002; Lemieux & Coe, 1995; M. B. Stein et al., 1997; for a review, see Shea, Walsh, MacMillan, & Steiner, 2004).

Cognitive Brain Event-Related Potentials

Several experiments have examined maltreated children's processing of emotional information utilizing psychophysiological paradigms. This research has focused on elucidating the possible mechanisms through which the chronic stress experienced by children who have been maltreated could eventuate in problems in the processing of emotion (Pollak et al., 1998). As discussed earlier in this chapter, attachment systems have been theorized to be constructed to permit flexible responses to environmental circumstances, influence and be influenced by emotion regulatory abilities, and function through internal working models that children have of themselves and of their relationships with others (Bowlby, 1969/1982; Cassidy, 1994). In the experiments described next, the investigators strived to ascertain whether the activation of these representations may be reflected through physiological activity as well as behavior.

The event-related potential (ERP) is an index of central nervous system functioning thought to reflect the underlying neurological processing of discrete stimuli (Hillyard & Picton, 1987). ERPs represent scalp-derived changes in brain electrical activity over time, obtained by averaging time-locked segments of an electroencephalogram (EEG) that follow or precede the presentation of a stimulus. In this manner, ERPs allow for monitoring of neural activity associated with cognitive processing in real time (Donchin, Karis, Bashore, Coles, & Gratton, 1986).

One particular ERP component, the P300, is a positive wave that occurs approximately 300 to 600 ms after the

presentation of a task-relevant stimulus and is maximal at the central-parietal scalp. The amplitude of the P300 varies as a function of task relevance and stimulus probability (R. Johnson, 1993) and has been utilized in conjunction with behavioral measures to classify specific cognitive operations such as the evaluation of stimulus significance. The P300 also may reflect processes involved in the updating of mental representations in working memory (Donchin et al., 1986). In general, such psychological processes serve to maintain accurate representations of one's environment by highlighting events that are significant.

Pollak and colleagues (1997, 2001) reasoned that the P300 component may be useful in illuminating the cognitive processes that accompany the encoding of salient emotional stimuli and highlight differences in such processes between maltreated and nonmaltreated children. The requirements of the task for both experiments were to recognize and respond to facial expressions of emotions. For all conditions, children were instructed to depress a hand-held button whenever they recognized the target facial expression. This emotional expression, the target, was only one of three emotions that were presented to the children (happy, angry, fearful). Across a variety of experimental conditions, children were required to attend to different facial expressions of emotion, and the probability of occurrence (rare or frequent) and task relevance (target or nontarget) were manipulated.

In the first experiment, Pollak and colleagues (1997) compared the ERPs of school-age maltreated and nonmaltreated children to a group of nonmaltreated children of comparable socioeconomic background and cognitive maturity. Children were instructed to respond to either a happy or an angry face. Because the amplitude of the ERP is influenced by the probability of occurrence of the stimuli, both happy and angry faces appeared infrequently (i.e., on 25% of the trials), whereas the nontarget neutral faces were displayed more frequently (i.e., on 50% of the trials). For both groups of children, there were few performance errors; thus, no distinctions could be made between emotion conditions (i.e., happy, angry, neutral) or between maltreated and nonmaltreated children with respect to accuracy or reaction time.

The ERPs of the nonmaltreated children were equivalent in both the happy and angry target conditions. The amplitude of the ERP was largest to the target stimuli, intermediate to the rare nontarget, and smallest to the frequent nontarget stimuli. In contrast, the ERPs of the maltreated children were larger in the angry than in the happy target conditions. The differential pattern of responding to emotion conditions suggests that, compared to nonmaltreated

children, different patterns of information processing were being evoked depending on the emotion to which the maltreated children were attending (Pollak et al., 1997).

Pollak and colleagues (1997) interpret these results as suggesting that angry and happy targets activated affective representations differentially for maltreated versus nonmaltreated children. They theorized that the ERP responses of the maltreated children reflected more efficient cognitive organization in the anger condition than in the happy condition. Such patterns of neurophysiological activation would be adaptive for coping with the stressful and threatening environments in which maltreated children reside (Cicchetti, 1991). However, biases toward negative affect or diminished responsiveness toward positive affect would place maltreated children at increased risk for encountering difficulties in their interactions with peers and adults (Dodge et al., 1997; Rieder & Cicchetti, 1989; Rogosch, Cicchetti, & Aber, 1995).

Emotion systems have been postulated to function as associative networks wherein input that matches significant mental representations activates memory systems (P. J. Lang, 1994). Pollak et al. (1997) conjectured, in this regard, that P300 amplitude may mark the match of facial stimuli with more complex affectively salient emotional memories. Theorists have invoked constructs such as schemas and working models to describe the mechanisms by which children integrate biologically relevant information with existing knowledge structures (Bowlby, 1969/1982; Cicchetti & Tucker, 1994). The findings of Pollak et al. provide corroborative empirical support for such hypothesized developmental processes.

Pollak and colleagues (2001) conducted a subsequent experiment in which they examined and compared the ERP responses of maltreated and nonmaltreated children to prototypic happy, angry, and fearful facial expressions. This investigation was conducted to determine the specificity of the relation between the ERP responses of the maltreated children and the nature of the eliciting stimuli. Specifically, Pollak and colleagues were interested in whether the ERPs of maltreated children generalized to positive versus negative emotional valence or were restricted to emotional displays of happiness versus anger. As we discussed earlier, negative emotions in addition to anger are frequently associated with maltreatment experiences. Thus, it is important to ascertain whether each discrete emotion may convey its own unique information and be processed in a distinct fashion.

Pollak et al. (2001) discovered that, as was the case in their earlier study, nonmaltreated children exhibited equivalent ERP amplitude responses to all of the target

facial expressions of affect. However, the ERP amplitude responses of the maltreated children exceeded those of the nonmaltreated comparison children only in response to the angry target, but not to the fear or happy targets. These results suggest that there was specificity in maltreated children's differential processing of the emotional information. The fact that the maltreated children's greater P300 amplitude to angry facial expressions was obtained only when these stimuli served as targets in a task indicates that when maltreated children's attention is deployed to angry facial expressions, these youngsters are uniquely sensitive in detecting this emotion expression over others (for further corroboration of this interpretation, see Pollak & Kistler, 2002; Pollak & Sinha, 2002; Pollak & Tolley-Schell, 2003).

Taken together, these ERP experiments demonstrate that the socioemotional, cognitive, and behavioral difficulties observed in maltreated children affect multiple neurobiological systems. Specifically, the ERP findings suggest that the nature of the experiences that maltreated children encountered during their lives caused particular stimuli to become personally meaningful, based, in part, on the stored mental representations that have been associated with the stimulus over time. As such, prior experiences of maltreated children are reflected in these children's psychophysiological responses.

In an investigation that is congruent with this interpretation, Schiffer, Teicher, and Papanicolaou (1995) utilized auditory ERPs to examine laterality and hemisphere integration of memory in adults who reported having been maltreated during their childhood. These formerly maltreated adults all were currently well functioning and had no current Axis I mental disorder. A group of adults without a history of childhood trauma and no current Axis I disorder served as comparison individuals. All participants were asked to actively recall a neutral or work-related memory and were subsequently asked to recall a disturbing affective memory from childhood.

In individuals without a history of childhood traumatization, the left and right cerebral hemispheres both were equally involved in the recall of these memories. In contrast, adults who recollected having been maltreated in childhood revealed dramatic differences. Specifically, during recall of the neutral memory, adults with traumatization histories in childhood exhibited a marked suppression of the ERP over the left cerebral hemisphere, characteristic of increased processing in the left hemisphere. While recalling the disturbing memory, the adults who had experienced childhood trauma displayed a shift in laterality, with the ERP becoming suppressed over the right hemisphere, an index of enhanced activation in the right hemisphere.

In sum, it is highly plausible that the stresses associated with child abuse and neglect may enhance the memory of emotionally salient stimuli in the environment (Howe, Cicchetti, Toth, & Cerrito, 2004; Howe, Toth, & Cicchetti, Chapter 15, this *Handbook*, Volume 2). Relatedly, as discussed earlier in this chapter, maltreatment also appears to affect children's interpretation and comprehension of particular emotional displays (Pollak et al., 2000).

BEHAVIOR GENETIC AND MOLECULAR GENETIC STUDIES

Conventional behavior genetic approaches to psychopathology utilize "natural experiments" in genetically informative designs (e.g., twin studies) to demonstrate the multifactorial nature of genetic and nongenetic (i.e., shared and nonshared environment) factors in the development of mental disorders. These quantitative behavior genetic investigations have enhanced our understanding of the etiology of psychopathology through estimating the genetic and environmental variance components of a number of mental disorders at various points in the life span (Rende & Plomin, 1995). In recent years, the role of child maltreatment in the development of antisocial behavior has been investigated in twin study designs. Jaffee, Caspi, Moffitt, and Taylor (2004) utilized a classic twin study design to examine links between child maltreatment and children's antisocial behavior. Participants were sampled from the representative birth cohort Environmental Risk Longitudinal Twin Study, and investigation focused on detecting the ways genetic and environmental factors shape child development (Trouton, Spinath, & Plomin, 2002). The investigators found that physical abuse played a causal role in the development of antisocial behavior in childhood. Furthermore, genetic factors did not account for any significant variation between monozygotic (MZ) and dizygotic (DZ) twins' experience of physical abuse, thereby discounting the possibility that any heritable characteristics of the children from their parents provoked physical abuse (Jaffee et al., 2004).

In another investigation that utilized a sample from the representative birth cohort Environmental Risk Study, Jaffee and colleagues (Jaffee, Caspi, Moffitt, Polo-Tomas, et al., 2004) sought to ascertain whether the impact of physical abuse on risk for conduct problems was greater among twins who had high genetic risk for these problems. Children's genetic risk for developing conduct problems was computed as a function of their cotwin's Conduct Disorder status and the pair's zygosity (MZ or DZ). Jaffee, Caspi, Moffitt, Polo-Tomas, and colleagues discovered that

the effect of physical abuse on Conduct Disorder was strongest for those children at highest genetic risk. Children who were physically abused who were at low genetic risk (i.e., DZ twins whose cotwin did not have Conduct Disorder) had a 2% probability of developing Conduct Disorder. In contrast, physically abused children at high genetic risk (i.e., MZ twins whose cotwin had Conduct Disorder) evidenced an increase of 24% in the likelihood of developing Conduct Disorder. Thus, the findings of Jaffee, Caspi, Moffitt, Polo-Tomas, et al. underscore that the prediction of psychopathology can achieve greater accuracy when both environmental pathogenic risk and genetic liability are simultaneously considered.

In recent years, a number of investigators have conducted molecular genetic studies of psychopathology with maltreated children. A major advantage of molecular genetic studies is that, in comparison to quantitative behavioral genetics approaches, they can elucidate specific genetic risk factors and the etiological mechanisms that link these risks with psychopathological and resilient outcomes (Cicchetti & Blender, 2004; Curtis & Cicchetti, 2003; Waldman, 2003). The confluence of several technological advances, including the ability to collect DNA using minimally invasive procedures (Freeman et al., 1997; Plomin & Crabb, 2000), more sophisticated genotyping methods (Craig & McClay, 2003; Watson & Akil, 1999), and the sequencing of the human genome (Venter et al., 2001), have enabled researchers to conduct investigations that only a decade earlier were possible only in our scientific imagination.

Caspi et al. (2002) examined how genetic factors contribute to why some maltreated children grow up to develop Antisocial Personality Disorder, whereas other maltreated children do not. In this longitudinal investigation of males who were studied from birth to adulthood, it was discovered that a functional polymorphism in the promoter of the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) moderated the effects of maltreatment. The MAOA gene is located on the X chromosome and encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, rendering them inactive. The link between child maltreatment and antisocial behavior was far less pronounced among males with high MAOA than among those with low MAOA activity. Maltreatment groups did not differ on MAOA activity, suggesting that genotype did not influence exposure to maltreatment.

Of relevance to research on the biological contributors to resilience (cf. Charney, 2004; Curtis & Cicchetti, 2003), it is conceivable that the gene for high MAOA activity may

confer a protective function against the development of Antisocial Personality Disorder in males who have been maltreated during their childhood. As described earlier in this chapter, maltreated children grow up in extremely stressful environments. The results of the Caspi et al. (2002) investigation suggest that a gene-by-environment (G×E) interaction helps to explain why some maltreated children, but not others, develop antisocial behavior via the effect that stressful experiences such as child maltreatment exert on neurotransmitter system development. Specifically, the probability that child maltreatment will eventuate in adult antisocial behavior is greatly increased among children whose MAOA is not sufficient to render inactive maltreatment-induced changes on neurotransmitter systems.

Foley et al. (2004) conducted an investigation with 514 male twins, ages 8 to 17 years, aimed at replicating the Caspi et al. (2002) study. The findings of this investigation replicated the major results of the Caspi et al. study. Specifically, low MAOA activity increased the risk for Conduct Disorder, but only in the presence of an adverse childhood environment, defined by interparental violence, parental neglect, and inconsistent discipline. Although there was a direct effect of familial adversity on risk for Conduct Disorder, there was not a main effect of MAOA genotype on developing Conduct Disorder. Once again, a G×E interaction is best supported by the results of this study. Furthermore, as with the Caspi et al. investigation, the predictive efficiency was vastly improved by including joint assessment of environmental risks and measured genes in the same study.

Caspi and colleagues (2003) conducted an investigation in which a functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene was shown to moderate the influence of stressful life events on depression. Specifically, individuals with one or two copies of the short (s) allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms, depressive disorders, and suicidality than individuals homozygous for the long (l) allele when confronted with high stress. The s allele in the polymorphic region is associated with lower transcriptional efficiency of the promoter compared with the l allele (Lesch et al., 1996).

Additionally, Caspi and colleagues (2003) found that adult depression was predicted by the interaction between the s allele in the 5-HTT gene-linked polymorphic region and child maltreatment that occurred during the 1st decade of life. The G×E interaction revealed that child maltreatment predicted adult depressive disorder only among individuals carrying an s allele (i.e., s/s or s/l) but not among l/l homozygotes.

Kaufman and colleagues (2004) conducted a study similar to that of Caspi et al. (2003); however, they extended Caspi's previous experiment by studying children. The results of Kaufman et al. that, in children, the *s* allele in the 5-HTT gene-linked polymorphic region confers vulnerability to depression only in individuals with a history of significant life stress replicates the G×E result found in Caspi et al. with adults. Furthermore, the findings of Kaufman et al. demonstrate that social support in concert with this genetic factor additionally moderates the risk for depression in maltreated children. Specifically, maltreated children who were homozygous for the *s* allele and who had a dearth of positive social supports had depressive symptoms that were nearly twice as high as maltreated children with the *s/s* genotype and positive social supports. The latter group of maltreated children had levels of depressive symptoms that were comparable to those of nonmaltreated children in the comparison group with the same *s/s* genotype.

The risk for depression in maltreated children was moderated by the interplay of genetic and environmental factors. Thus, the negative developmental sequelae associated with child maltreatment are not inevitable. As discussed earlier in this chapter, there are many factors that contribute significantly to the ultimate developmental course embarked on by maltreated children. Of particular importance, the quality and availability of social supports were environmental factors that promoted resilience in maltreated children, even in the presence of a genotype that might otherwise be expected to confer vulnerability to psychiatric disorder.

INTERVENTION/PREVENTION

Despite the undisputed empirical evidence for the high risk of maladaptation as a developmental consequence of child maltreatment, there has been a paucity of theoretically informed intervention and prevention programs (Reppucci, Woolard, & Freid, 1999). Prevention efforts in the United States emanated from the areas of public health, epidemiology, and community psychology, initiated by the passage of the Child Abuse Treatment and Prevention Act in 1974. Early prevention efforts were largely geared toward increasing public awareness and acceptance of the problem of child abuse and neglect and involved tactics such as the use of public service announcements on television and radio (Daro & Donnelly, 2002) to disseminate information about child maltreatment. As a result of these efforts, public opinion surveys in the 1980s revealed that over 90% of the

public was aware of the problem of child maltreatment and could recognize that both societal and individual factors may contribute to its emergence (Daro & Gelles, 1992). Perhaps reflective of increased public knowledge about child maltreatment, concurrent epidemiological investigations revealed substantial increases in reports of suspected child maltreatment (McCurdy & Daro, 1994).

Although the efforts that were put forth were important from a public health perspective, little developmental influence was present in the conceptualization, implementation, or evaluation of these initiatives (Cicchetti & Toth, 1992; Toth, Maughan, et al., 2002). Early on, Zigler (1976) called for prevention efforts to consider the ecological context, predicting that single service models, which focused exclusively on the parent-child dyad, were overly simplistic and doomed to failure. Consequently, Zigler, among others, influenced the research field toward the adoption of more complex ecological transactional frameworks to guide both developmental theory and etiological theory on child maltreatment and, as an extension, called for such theory to inform intervention and prevention efforts (Belsky, 1980; Cicchetti & Lynch, 1995; Cicchetti & Rizley, 1981).

Intervention efforts have been slow, however, to incorporate theory-driven intervention and prevention programs, and even slower to apply an ecological-transactional model to such initiatives. Instead, the majority of studies that evaluated the effectiveness of prevention for maltreatment have focused on short-term behavioral strategies. Initial empirically tested prevention investigations were rooted in didactic instruction with parents, which have been shown to be rather ineffective (Daro, 1988), or home visitation programs, involving behavioral techniques such as modeling, practice, and feedback, to provide preliminary support to mother-child dyads during the 1st year of life (Kempe, 1976). For example, Olds and Henderson (1989) developed a home visitation prevention for mothers considered to be at risk for maltreating their infants. Young, single, low SES, pregnant women were assigned to one of two conditions: to receive home visits by nurses from pregnancy through the child's 2nd year or to receive comparison services. Results indicated a 50% reduction in child abuse and neglect among families in the treatment condition. In a 15-year longitudinal follow-up of this investigation (Olds et al., 1997), with nearly 80% of the women in their original study, women who had received the home visitation during pregnancy were less likely to be identified as perpetrators of child abuse or neglect or to be recipients of Aid to Families with Dependent Children than were women in the comparison group. Similar findings have been replicated by Kitzman et al. (1997).

Given these encouraging rates, the implementation of home visitation was expanded by the Healthy Families America (HFA) program, which sought to increase the availability of high-quality home visitation services and to create communitywide commitments to these services. Findings from this research initiative report that HFA programs may be successful in improving parent-child interactions but have more limited success in other areas, such as the prevention of child abuse and neglect. Moreover, HFA programs did not demonstrate significant improvements in children's development or social support (Daro & Harding, 1999), thus providing an impetus for researchers and practitioners to move beyond a narrow focus to consider the communitywide and national context.

Considering the impact of the family on both the onset of maltreatment as well as preventive efforts (Hays & Jones, 1994), recent prevention efforts have focused on the parents, seeking to provide social support and promote positive parenting (cf. Daro, 1990; Gaudin, Wodorski, Arkinson, & Avery, 1990; Olds, Henderson, Chamberlin, & Tatelbaum, 1986). For example, one recent randomized clinical trial was conducted to test the efficacy and sufficiency of parent-child interaction therapy in preventing re-reports of physical abuse among abusive parents (Chaffin et al., 2004). This investigation involved three intervention conditions: parent-child interaction therapy (PCIT), PCIT plus individualized enhanced services, and a community standard intervention. Based on social learning theory, the goal of using PCIT with abusive parents is to disrupt the escalating coercive cycles that are believed to characterize the maltreated children's family interactions (Patterson, 1976; Patterson & Reid, 1984; Patterson, Reid, & Dishion, 1992; Urquiza & McNeil, 1996). Results indicated that fewer parents in the PCIT groups had re-reports of abuse at follow-up (850 days) compared to the parents in the community standard condition; however, the additional services did not improve the efficacy of PCIT (Chaffin et al., 2004).

Alternatively, an investigation of a multilevel selected primary prevention of child maltreatment (L. Peterson, Tremblay, Ewigman, & Saldana, 2003) combined multiple perspectives on intervention techniques by including modeling, role-playing, Socratic dialogue, home practice, and home visits. Specifically, this intervention targeted improvements in parenting skills, developmentally appropriate interventions, developmentally appropriate beliefs, improving negative affect, acceptance of a responsible parent role, acceptance of a nurturing parent role, and self-efficacy. Successful intervention effects were noted at each level of the model, and effects remained at 1-year follow-

up. Although a major strength of this intervention was its multimodal approach, it still targeted only a unidimensional aspect of child maltreatment by focusing on parental perceptions and behaviors.

In isolation, these treatments are likely to offer an incomplete solution to the problem of child maltreatment. Consistent with a developmental psychopathology perspective, unidimensional approaches to treatment are inadequate (Cicchetti & Toth, 2000; Toth & Cicchetti, 1993, 1999), whereas a comprehensive multidimensional approach to treatment would be better able to address the multiple domains in which maltreated children face vulnerability factors, placing them at increased risk for later maladaptation. The focus of interventions in child maltreatment, however, has largely been devoted to working with and addressing the problems of the maltreating parent to alleviate the risk for continued maltreatment, in isolation from other factors. The recurrence rates of child maltreatment provide the most solid support for the inadequacy of this approach, such that child welfare re-report rates of 40% or more within a few years are common. Notably, many of these re-reports are among physically abusive parents and are for recurrent physical abuse (DePanfilis & Zuravin, 1999; Way, Chung, Jonson-Reid, & Drake, 2001).

To begin to address the limitations of parent-focused treatments, interventions that are informed by developmental theory are being advocated for maltreated children (Cicchetti & Toth, 1993; Toth & Cicchetti, 1993; Toth, Maughan, et al., 2002). As theorized by this approach, clinicians may facilitate parents' understanding of their children's behavior by focusing attention on the manner in which children are negotiating stage-salient developmental issues. Thus, parenting interventions may be attuned to the resolution of these stage-salient developmental tasks.

With regard to the development of early attachment relationships, a number of attachment-informed interventions have been developed and hold promise for treatment in the area of abusive and neglectful parenting (M. F. Erickson, Korfmacher, & Egeland, 1992; Lieberman, Weston, & Pawl, 1991). Interventions that are informed by developmental theory often conceive of the mother-child attachment relationship as central to positive child outcomes (Fraiberg, Adelson, & Shapiro, 1975; Lieberman, 1991). In this infant-parent psychotherapy approach, mother and infant are seen together in sessions with a therapist, typically held in the client's home. A therapeutic relationship is formed, and through joint observation, the therapist tailors developmental guidance to the mother's level of functioning. Therapy includes exploration of the mother's own attachment organization and developmental experiences, in

addition to her perceptions and reactions to her child, and the manner in which mother-child relate. Through reflection, redirection, and interpretation, the therapist strives to alter distortions in the mother-child relationship with the goal of changing internal representational models. A number of investigators have attempted to promote attachment security in samples of low-income mothers and their young children (see Lieberman & Zeanah, 1999, for review). Recognition of the importance of fostering maternal sensitivity and developmentally appropriate responsiveness to children were central themes across all studies. Meta-analysis reveals, however, that the outcome data are inconsistent (van Ijzendoorn, Juffer, & Duyvesteyn, 1995), leaving questions about the efficacy of such intervention approaches.

Given the inconclusive evidence on the efficacy of interventions that are didactic versus dyadic, Cicchetti, Toth, and Rogosch (2005) conducted a randomized preventive intervention trial in which 12-month-old maltreated infants and their mothers were assigned to one of three intervention groups: (1) a psychoeducational home visitation (PHV) that focused on enhancing maternal knowledge of basic child development and improving parenting while reducing maternal stress and increasing maternal social supports; (2) an attachment theory-informed intervention, named infant-parent psychotherapy (IPP); and (3) the community standard (CS), which consisted of treatment typical of what was available in the community for maltreating families. Additionally, an equally socioeconomically disadvantaged nonmaltreated comparison (NC) group was matched to the three intervention groups. At baseline, infants from maltreating families exhibited a greater percentage of insecure attachment than did the infants from nonmaltreating families; the majority of the insecurity was classified as disorganized (Type D) attachment. Postintervention, approximately 1 year later, the infants from the PHV and IPP interventions both evidenced a significant change in their attachment security from baseline such that their attachment security no longer differed from the infants from nonmaltreating families. In contrast, the infants from the CS group demonstrated no improvement in their attachment security. These results have far-reaching implications as they demonstrate that disorganized attachment in maltreated infants can be modified through early intervention. Moreover, the equal effectiveness of the PHV and IPP interventions suggest that intervention efforts during infancy do not necessarily need to directly focus on attachment to improve this developmental domain.

Utilizing a similar treatment design, Toth, Maughan, et al. (2002) compared the relative efficacy of two inter-

ventions in altering maltreated preschool children's representational models. By incorporating a psychoeducational didactic treatment condition as well as a parent-child psychotherapy condition, this investigation was one of the first to allow for direct comparison between the effectiveness of these methods within a single design. Maltreating families were assigned to either preschooler-parent psychotherapy (PPP), psychoeducational home visit (PHV), or a CS condition, and an NC group served as an additional control condition. Children in PPP intervention evidenced more of a decline in maladaptive maternal representations over time, as assessed through story stem narratives, than did children in the PHV and CS conditions. In addition, PPP children displayed a greater decrease in negative self-representations than did children in the CS, PHV, and NC groups. Mother-child relationship expectations of PPP children became more positive over the course of intervention compared to NC and PHV. In contrast to interventions that target maltreated children in infancy (Cicchetti et al., 2005), the results of this study suggest that an attachment theory-informed model of intervention (PPP) is more effective at improving representations of the self and of caregivers than is a didactic model of intervention (PHV) directed at parenting skills. The major limitation of this study, however, was its exclusive focus on representations and not other outcomes such as parental knowledge about developmentally appropriate expectations, which may have had more substantial gains in the PHV group. Additional outcome measures would greatly inform our understanding of advantages and disadvantages of each approach to intervention.

Undoubtedly, more research is needed to further inform intervention and prevention efforts. As presented in the previous sections, maltreating parents exhibit a complex pattern of cognitive, affective, interpersonal, and behavioral processes that are in part derived from their own childhood relational experiences. Parental resources are further challenged by the influence of macrosystem factors as well as by poverty, community violence, and other aspects of the exosystem. For example, a recent study by Slack et al. (2004) revealed that indicators of poverty such as perceived material hardship and infrequent employment and parenting characteristics such as low parental warmth, use of physical discipline, and allowing children to engage in frequent television viewing are predictive of child neglect. Moreover, parenting characteristics did not mediate the relationship between perceived hardship and incidence of neglect. Thus, the implication for intervention and prevention is to address the material needs of families; given its link to child neglect over and above parenting character-

istics, interventions that address only the parenting aspect of neglect may be ineffective.

Preventive programs in the community are also important for promoting competent parenting and reducing maltreatment. These programs typically strive to promote competence and sensitivity in parents and to improve their coping strategies with regard to stressful living conditions (Wolfe, 1993) by enhancing their social support system. For example, self-help groups, crisis intervention, and in-home services that are community agencies may reduce the incidence of problematic parenting and maltreatment, thereby reducing the need for more intensive intervention services when maltreatment does emerge (Wolfe & Wekerle, 1993).

Reduction in the rate of maltreatment has also been associated with participation in early school-based interventions, such as child-parent centers in the Chicago Longitudinal Study (Reynolds & Robertson, 2003). The child-parent centers provided child education and family support services in high-poverty areas. Participation in the program for 4 to 6 years was associated with significantly lower rates of maltreatment than participation in alternative kindergarten interventions.

Finally, knowledge gained from research on resilience among maltreated children is especially relevant to the development of intervention and prevention efforts (Luthar & Cicchetti, 2000). As resilience research identifies mechanisms that contribute to positive adaptation in the face of adversity, prevention and intervention programs may be tailored to capitalize on and enhance these processes in at-risk children. Consistent with an ecological-transactional model, these adaptive processes may derive from multiple levels of the ecology, including family, community, and cultural features, in addition to individual characteristics (Cicchetti & Rogosch, 2002). Moreover, Luthar and Cicchetti argue that because resilience is an ongoing dynamic process, preventions that are designed to promote resilience will likely be most effective as long-term programs that support children through successive periods of development.

Undeniably, there is a need for sufficient breadth in intervention and prevention programs that can address the complex developmental consequences of maltreated children as well as the parenting practices, relationship disturbances, and extensive needs of these families (Cicchetti & Toth, 1993, 2000; Olsen & Widom, 1993). The wide variety of techniques that have been applied to intervention efforts, ranging from nondirective play therapy to behavior modification, speaks to the multifinality of experience of maltreated children (Cicchetti & Rogosch, 1996) and to the

notion that no one treatment paradigm will be equally appropriate for all maltreated children.

CONCLUSION AND FUTURE DIRECTIONS

In this chapter, we argued that the experience of child maltreatment, and the concomitant poor-quality parental care received by these children, exert a deleterious impact on psychological, genetic, and biological processes. Moreover, studies suggest that genetic and neurobiological factors may mediate or moderate the relationship between maltreatment and behavior.

A number of developmental processes have been postulated to exert an impact on the nature of brain-behavior relations: (1) aspects of the external environment that are atypical for most members of a species, (2) the specific type and amount of input received, and (3) the existence of biases for orienting toward particular classes of stimuli in the external environment (J. Black et al., 1998; Cicchetti, 2002; Dodge et al., 1997; R. Johnson, 1993).

In addition, the literature reviewed in this chapter has revealed that multiple psychological and neurobiological systems appear to be affected by the experience of child maltreatment. Clearly, multiple methods and approaches are necessary to explain the complex interplay between developing individuals and their maltreating environments. However, to date, most investigations of the neurobiological consequences of child abuse and neglect have examined one neural system. Similarly, many studies of the psychological sequelae of child maltreatment have focused on one domain. In the future, it will be essential to undertake investigations of maltreated children that examine multiple levels of psychological and neurobiological functioning and that employ multiple methods (cf. Cicchetti & Dawson, 2002).

The present maltreated versus comparison group differences approach needs to be augmented by an equal focus on individuals. Although groups of maltreated children differ from groups of nonmaltreated children on most of the psychological and neurobiological structures and functions investigated thus far, not all maltreated children are affected by their experiences in the same manner. Moreover, the neurobiological and psychological functioning of some maltreated children appears not to be negatively affected (Cicchetti & Rogosch, 2001a, 2001b), or it may be reflective of an enhanced neural plasticity in resilient individuals (Cicchetti & Rogosch, 1997; Curtis & Cicchetti, 2003). We do not know if the neurobiological structural and/or functional difficulties displayed by some maltreated children are permanent or irreversible, or, if reversible, when and to what

degree. Additionally, we do not possess the knowledge regarding whether some to-be-identified neural systems may be more plastic than other neural systems that may be more refractory to change or have a more time-limited window when neural plasticity can occur. Thus, a person-oriented approach (Bergman & Magnusson, 1997; von Eye & Bergman, 2003), in which multiple neurobiological and psychological systems are studied within individuals over developmental time, should also be implemented in future research on the effects of maltreatment on biological, genetic, and psychological processes. In this manner, we can acquire vital information on how the neurobiological systems of maltreated children develop at different periods, as well as when such developing neural systems may be most vulnerable in different profiles of individuals who share similar aspects of neurobiological and psychological functioning and who may range from none or minimal damage to major neurobiological and psychological dysfunction.

Even in instances of long-term damage, the neurobiological and psychological consequences of maltreatment may not prove to be irreversible. Because postnatal brain structuration and neural patterning are thought to occur, in part, through interactions and transactions of the child with his or her environment, changes in the internal and external environment may lead to improvement in the ability of the individual to grapple with developmental challenges. Thus, although genetic and historical developmental factors canalize and constrain the adaptive process to some degree, it is conceivable that behavioral and neural plasticity are possible throughout the life course as a result of adaptive neural and psychological self-organization (Cicchetti, 2002; Cicchetti & Tucker, 1994; Curtis & Cicchetti, 2003). Additionally, pharmacological and behavioral/psychological interventions can be implemented to modify the structure and function of the brain and to ascertain how the structural and functional changes that are produced will change the ability of the brain to process the information it confronts during stressful situations. Successful interventions should alter behavior and physiology by producing changes in gene expression (transcription) that produce new structural and functional changes in the brain (Cicchetti & Blender, 2004; Kandel, 1999).

To achieve these goals, a number of additional advances in research on the neurobiological and psychological consequences of child maltreatment must be implemented in the future. First, sample sizes must increase in order for there to be sufficient statistical power to detect differences in multiple-level-of-analysis, multimethod, cross-sectional, and longitudinal investigations. Second, much of the scien-

tific literature published to date on the neurobiology of child maltreatment has focused on hospitalized samples. Many of these maltreated individuals also have comorbid mental disorders and/or use or abuse substances and alcohol (cf. DeBellis, Keshavan, et al., 1999). Moreover, maltreated children in hospitalized samples also are receiving pharmacological and/or psychotherapeutic interventions. Although one can attempt to control for these factors statistically, their presence makes it difficult to disentangle the effects of maltreatment on brain structure and function from other competing conditions (e.g., mental illness, drug abuse, intervention) on the neurodevelopmental anomalies (or lack thereof) found in hospitalized maltreated children. It also will be essential for future research utilizing neuroimaging technologies to examine brain structure and function in community samples of maltreated children.

To comprehend neuropsychological development, it is essential to recognize that the brain is a mutable organ and that its structural organization reflects both what is important to the individual (i.e., the history of the organism) and what the individual is capable of at that particular time in development (Luu & Tucker, 1996). Thus, neuroscientists utilizing neuroimaging techniques to examine neurobiological structures in maltreated children must move beyond the descriptive anatomical level of structural MRI and begin to incorporate fMRI technology into their research armamentaria. Because the brain is a dynamic, self-organizing system that is mutable, future neuroimaging research should ascertain whether the brain structures and brain functioning of maltreated children designated as resilient through psychological criteria (see, e.g., Cicchetti & Rogosch, 1997) differ from those of nonresilient maltreated children. Increasingly, research on the correlates of and contributors to resilient functioning should incorporate multiple biological levels of analysis (e.g., HPA axis functioning, including stress-reactivity paradigms and diurnal regulation assessments; EEG coherence; EEG hemispheric activation asymmetries; acoustic and emotion-potentiated startle; ERPs); and neuroimaging methods, including MRI, MRS, diffusion tensor imaging, magnetoencephalography, and fMRI, and not merely focus on psychological processes (see Curtis & Cicchetti, 2003, for an elaboration).

Finally, because research with rodents and nonhuman primates has revealed that social experiences, such as maternal caregiving behaviors, maternal deprivation, and maternal separation, affect gene expression as well as brain structure and function (Kaufman & Charney, 2001; Levine, 1994; Meaney et al., 1996; Sanchez, Ladd, & Plotzky, 2001), it is quite likely that child maltreatment affects

the expression of genes that impact brain structure and function as well as basic regulatory processes.

IMPLICATIONS FOR INTERVENTION

As knowledge on the psychological and biological sequelae of maltreatment, as well as their interrelation, continues to accrue, it is critically important to implement scientifically rigorous randomized clinical trial preventive interventions with maltreated children and their caregivers. The time has come to conduct interventions that not only assess behavioral changes but also ascertain whether neurobiological structures and functioning are modifiable or refractory to intervention. There is growing evidence that successful intervention modifies not only maladaptive behavior but also the cellular and physiological correlates of behavior (Cicchetti & Posner, 2005; Kandel, 1998, 1999). The fact that interventions are able to bring about beneficial effects beyond the early years of life suggests that there is a psychobiology and a neuropsychology of hope and optimism for maltreated children that can minimize or eradicate the adverse effects of their histories. Furthermore, just as knowledge of genetic predisposition to medical illness can result in the modification of behavior so as to minimize the expression of genes associated with medical illness, so, too, might knowledge of the effect of maltreatment on gene expression and a related genetic vulnerability to mental illness serve to help individuals alter their life course so as to inhibit the expression of genes that are associated with maladaptation and psychopathology. Moreover, it is conceivable that successful interventions may activate genes that protect maltreated individuals from pathological outcomes and promote resilient functioning.

Research that has found increased cortisol concentrations in children who have experienced multiple subtypes of maltreatment also underscores the critical need to provide intervention for these children given their risk for the emergence of impairments in cognitive, memory, and affective functioning (Cicchetti & Rogosch, 2001a; see also Sapolsky, 1992). Because of increasing economic pressures and resultant treatment availability to only the most impaired individuals, findings on HPA axis functioning in maltreated children could be used to help lobby for service availability. Increased cortisol levels in maltreated depressed children also indicates that interventions targeted at reducing depressive symptoms are especially important for children who have experienced abuse and neglect.

Work that suggests there may be neuronal loss in instances of prolonged maltreatment (DeBellis et al., 2000)

has both treatment and policy implications. Given the severe biological and psychological consequences of chronic maltreatment, there must be intensified efforts to either treat the maltreating family system effectively within a specified period of time, or to move toward placing the child in a safer environment.

The fact that child maltreatment exerts its influence on developmental processes at various levels of the ecology (Cicchetti & Lynch, 1993) highlights the importance of intervening in all components of the ecologies of children who have been abused and neglected. For example, because child maltreatment and community violence influence and transact with individual functioning to result in sustained adversity and disturbances in development (Lynch & Cicchetti, 1998), interventions must be directed at the contextual adversity that children from impoverished neighborhoods are likely to encounter. Ideally, the entire exosystem (e.g., schools, churches, neighborhood centers) should be marshaled to adequately deal with the pervasive influences that may compromise the development of maltreated children.

A crucial issue that can be informed by research on neuropsychological and psychophysiological functioning in maltreated children is determining whether the timing of interventions matters. A major implication of a dynamic developmental systems approach is that the implementation of intervention following the experience of trauma should ameliorate the intensity and severity of the response to the trauma, as well as the developmental course (Toth & Cicchetti, 1993, 1999). Such interventions that are closely timed to trauma, maladaptation, and disorder onset also should decrease the probability of developing, in a use-dependent fashion, sensitized neural systems that may cascade across development (Cicchetti, 2002). This is not to suggest that if intervention is *not* time-tied to the trauma, it will ultimately fail. Rather, one may need to ascertain alternative treatment methods that will address the sequelae of the maltreatment experience. Moreover, if a long-term course of trauma has occurred and a significant period of time has passed, it may be counterproductive to continue to revisit the trauma.

Although we possess more knowledge regarding the etiology and sequelae of child maltreatment than at any other point in history, it is crucial that researchers continue to design and conduct the scientific investigations that are necessary to provide definitive answers to the complex questions that remain concerning the effects of child maltreatment on psychological and neurobiological functioning and on gene expression. The knowledge gleaned from these

studies will enable maltreated children to receive interventions that are based on sound scientific research. Furthermore, the translation of basic behavioral and neuroscience investigations into the development of preventive interventions will be inordinately helpful in reducing the burden of mental illness associated with this grave societal ill.

Questions about whether and by what mechanisms early exposures and experiences may have lasting effects on the organism are fundamental to the field of developmental psychopathology and constitute a substantial focus for research in the neuroscience fields. The history of this debate from the previous century through today illustrates how dramatically concepts concerning psychological development may be supplanted, updated, or reissued. Indeed, in the course of addressing this topic, a full range of opinion has been expressed, with extreme nativism on one hand and extreme environmentalism on the other.

Several themes are evident in contemporary research on the effects of early experience on later psychological development. The first is the amount of research dedicated to the issue. Recent interest is not so noteworthy in the animal research, which for decades has considered this question; rather, it is the attention directed toward this topic in

human research that is most notable. A second major theme is the weight placed on the possibility that there may be lasting effects of early experiences or exposures on psychological outcomes. That shift in emphasis reflects a growing trend toward translational research, greater sophistication in understanding the putative biological mechanisms that may be at work, and improved technology to detect potential effects. A third theme is the growing significance of the early experiences debate for policy and practice. That is seen in popular and academic books as well as in clinical settings, such as the adjustment of children who experienced early deprivation. These themes resurface throughout this chapter.

This chapter has several aims: (1) to examine key conceptual models that have been proposed to account for why, or why not, early experiences and exposure would have persisting effects on psychological development;

(2) to review some of the conceptual and methodological lessons that have been learned from existing studies of early experience; (3) to review several major lines of research that offer some of the strongest evidence of a persisting effect of early experience on psychological development; and (4) to evaluate what implications the study of early experience has for intervention and prevention. A concluding section considers some of the future directions for research in this area.

For the purposes of this chapter, “psychological development” is restricted to behavioral and other outcomes with a prominent cognitive-affective component; it is not meant to include all outcomes associated with brain processes. Thus, there are many lines of investigation that have a prominent place in research on early experience that are not covered (e.g., vision). Reference to these later outcomes and other health outcomes is considered only sporadically throughout the chapter.

CONCEPTUAL MODELS OF EARLY EXPERIENCE

Several conceptual models underlie research on early experiences. Three broad classes of models are considered here: sensitive period models, adaptive or programming models, and life course models. Inevitably, given space limitations and the broader aims of this chapter, it is necessary to simplify the definition and description of these models. These models are chosen as exemplars of developmental hypotheses about the role of early environmental experiences and exposures because they have generated and attracted considerable research in the animal and/or human literature, there are well-established paradigms to test their predictions, and there is ample available data to evaluate their claims.

Other models in the developmental neurosciences have been proposed but are not covered here. For example, the diathesis-stress model is not included because it is not inherently developmental; that is, in its basic form, the general diathesis-stress model is not fundamentally concerned with the proposition that some features of development may, *per se*, constitute a diathesis or that the effects of stress on a preexisting vulnerability are moderated by psychological or biological development. For somewhat parallel reasons, the experience-dependent model (Greenough, Black, & Wallace, 1987) is not included here insofar as it is primarily concerned with showing that there is a biological change following experience rather than how the developmental stage of the organism influences the type of envi-

ronmental input needed, the immediacy of the input, or the effects on subsequent development if inadequate environmental input is provided. Last, because the concern in this chapter is with hypotheses about if and how early experiences shape development, all the models covered here propose that environmental input is important in shaping individual differences and species-typical development. Extreme nativist models that presume that healthy maturation occurs without regard to environmental input or models that make no particular predictions about transactions between the organism and the environment are not covered in any detail. These latter models provide a sort of null hypothesis against which are set the sensitive period, programming, and life course models discussed in detail.

This review contrasts multiple models for understanding the effects of early experiences on psychological development according to four dimensions:

1. Individual differences versus species-typical development;
2. The nature of the environmental input, that is, how readily identified the input is and what magnitude of effect is presumed;
3. The putative role of psychological and/or biological mechanisms and the prominence of human versus animal studies; and
4. resilience and the likelihood of recovery following intervention. These dimensions were chosen because they describe an important element and implication of each model and provide a basis for distinguishing these models empirically. These four dimensions are not meant to completely characterize each model, but to provide a conceptual and methodological framework that will need to be kept open for revision.

Sensitive Period Models

Sensitive period models hypothesize that there is a period in the ontogeny of the organism in which environmental input is needed for normal development to proceed. A sensitive period may exist for each of several types of development within the same organism, from visual acuity to attachment; also, different species might be expected to show different sensitive periods—in terms of onset and length—for the same behavior. These latter two positions follow from the proposal that the sensitive period is determined by the active period of brain development linked with a particular behavioral or biological outcome.

How rigidly defined the period of sensitivity is remains uncertain, at least in most instances. Recent work in this

area has, in fact, sought to extend the boundaries of the sensitive period, thereby rejecting the rigid boundaries governing sensitive periods that were often initially presumed. The net effect of these efforts has been to retain the sensitive period concept while also removing the condition that the sensitive period is necessarily rigidly defined.

Different terms have been used to express the hypothesis that there is a period in ontogeny at which certain environmental input is essential to ensure normal development; these terms include critical period (e.g., Bornstein, 1989), sensitive period, and experience-expectant (Greenough et al., 1987) models. There may be important differences among these terms, but they are considered in the same class of models here because they have been used interchangeably in the literature (particularly sensitive period and critical period), and, fundamentally, each sets up an expectation for the association between normal development and environmental experience.

Also, although sensitive periods are most frequently associated with early development, they may be found throughout the life course, such as a parent bonding with an offspring, as has been shown in the animal literature (Fleming, O'Day, & Kraemer, 1999).

There is growing evidence that sensitive or critical periods are under genetic control (Hensch, 2004). In one example (Huang et al., 1999), mice genetically manipulated to overexpress brain-derived neurotrophic factor (BDNF) showed accelerated development and early closure of the critical period in the visual cortex. These data suggest that genetically mediated processes regulate critical periods for species-typical development. A complementary proposal, that environmental exposure in a sensitive period in development may alter gene expression, has also been reported (Kinnunen, Koenig, & Bilbe, 2003). Thus, a picture is emerging of a dynamic interplay between environmental experience and genetics, and there is little doubt that this line of investigation will yield additional important insights into how sensitive periods are best conceptualized.

A final consideration for defining sensitive period models is their evolutionary basis. Most would assume that there is evolutionary significance to the existence of sensitive periods; for example, it might not be adaptive for the organism to be equally and endlessly mutable. In addition, as Berardi, Pizzorusso, and Maffei (2000) showed for the effects of monocular deprivation across several species, there is a very tight positive connection between the length of the critical period and the age span of the species. So, at least for visual acuity, the message is not that there is *not* a critical/sensitive period in humans as there is for animals, but rather that it is longer. Whether or not that lesson ap-

plies to other areas of development, such as attachment, remains to be seen and is considered later.

Individual Differences versus Species Typical Development

Sensitive period models are concerned with species-typical development, that is, the presence versus the absence of some essential behavior; the distinction in outcome is between normality and gross pathology that might seriously undermine species survival and adaptation. Thus, in research examples of sensitive periods, such as birdsong (Thorpe, 1963), vision (Hubel & Wiesel, 1970), imprinting, and social attachments (Harlow & Suomi, 1970; Insel, 1997), the animals that did not receive the normal or expected input were not merely disordered but showed fundamental deviations. Research of this sort, because of its emphasis on species-typical versus clearly aberrant development, is targeted to elucidate core principles about the organism; in contrast, there is much less (if any) interest in accounting for differences among individuals in behavior within the normal range.

Nature of the Environmental Input

Sensitive period models assume a major impact of the environment. The focus in research has tended to identify what dose of environmental input is required, what specific type of environmental input or experience is necessary for normal development to proceed, and when in development that input is most necessary. A major tactic in answering these questions is to expose animals to pathogenic environments (e.g., deprivation) rather than to gradients of environmental quality across the spectrum, although that is now changing somewhat. The tendency to study the effects of obviously pathogenic environments that manipulate dose, type, or timing of exposure may be partly explained by the early interest in assessing the extent to which putatively "instinctual behavior" required *any* environmental input. Consequently, a major aim in studying the organism's early experience was to identify the minimum threshold of environmental effect—the point at which the organism would acquire or develop species-typical behavior. The environmental dose of interest was the minimum necessary for the organism to develop apparently normally.

A second, related reason research adopting a sensitive period model focuses on the minimum threshold for normal development is that the outcomes of interest would be expected to be protected or canalized (Gottlieb, 1991). If that is the case, then it might follow that there may be comparatively modest demands on the environment for normal development to proceed. That is, if a particular function were

so important to the normal development of the organism (e.g., reproductive fitness), then it might make little evolutionary sense for these outcomes to hinge on highly particular demands on the environment in terms of quality or quantity. Therefore, although sensitive period models place great importance on environmental input, they set a low demand threshold on what kind of input is needed or “good enough.”

The Role of Psychological Mechanisms and the Prominence of Human versus Animal Studies

With few exceptions (e.g., vision and language; Itard, 1962; Johnson & Newport, 1989; Maurer, Lewis, Brent, & Levin, 1999), sensitive period models have not had a major influence on the study of human development. For those aspects of human research that have considered sensitive period models, the focus is on biological rather than psychological mechanisms. Claims that there may be a sensitive period for psychological (especially behavioral) outcomes are exceedingly rare and, to date, without solid foundation. Instead, studies testing sensitive period hypotheses are based almost exclusively on animal experimentation (e.g., Bornstein, 1989) and invoke a variety of alternative biological mechanisms.

Notwithstanding the lack of evidence for psychologically sensitive periods, there is ample evidence that biologically mediated sensitive periods exist for psychological or psychiatric phenotypes. For example, there is a link between exposure to rubella infection during the first trimester and an increased incidence of Autism Spectrum Disorders (Chess, 1977); also, nutritional deprivation in utero has been linked with major mental illness in adulthood (Brown, van Os, Driessens, Hoek, & Susser, 2000). These examples suggest that the search for sensitive periods for psychological development may benefit from adopting a broader biological model that may underlie psychological outcomes.

Likelihood of Recovery or Resilience

Just as there may be periods of ontogenetic vulnerability (Schneider, Roughton, Koehler, & Lubach, 1999), there may be periods of ontogenetic opportunity for intervention. That is, if a sensitive period for a particular outcome did exist, then interventions would need to be delivered during that sensitive period. Interventions delivered outside the sensitive period would have much less, if any, effect on the outcome of interest. Alternatively, a particular intervention might have a *different* effect depending on when in development it was delivered. Thus, the timing of the intervention is the key factor, according to a sensitive period

model. Also, according to a sensitive period model, the organism expects only “adequate” rather than “enriched” input for normal development to proceed. Enriched environments may have an effect if provided during a sensitive period, but are not portrayed as necessary for the acquisition of normal function. Indeed, given the lack of interest in individual differences, it is not surprising that little interest has been shown in resilient or supercompetent levels of functioning.

Lorenz’s (1982) experiments on imprinting provide one of the better-known examples of how “treatment-resistant” an organism may be to interventions delivered after a sensitive period. He showed that those animals that imprinted (notably, on Lorenz himself) did not exhibit signs of subsequent imprinting on a member of the same species when it was introduced after the sensitive period; neither did the animals show any reduction in imprinting on Lorenz. Primate research also shows that timing of treatment is important and that degree of recovery is limited. For example, the effects of early deprivation on social behavior (e.g., Harlow & Harlow, 1969) are at best modestly remediable, with the likelihood of success depending on the timing of the intervention (Cameron, 2004; Martin, Spicer, Lewis, Gluck, & Cork, 1991; S. L. Ramey & Sackett, 2000). Other primate research demonstrates that the effects of early maternal deprivation persist into adulthood and are transmitted intergenerationally (although, interestingly, improvements in mothering were observed with second-born offspring without any intervention other than [poorly] mothering the first born; Ruppenthal, Arling, Harlow, Sackett, & Suomi, 1976). It is not known if there are comparable examples of treatment timing in humans. This possibility is gaining attention, particularly in the context of children who experienced severe and profound early deprivation.

Experience-Adaptive or Developmental Programming

There is now substantial evidence that the biology of the fetus and child adapts to its environment (Amiel-Tison et al., 2004a, 2004b; Bateson & Martin, 1999; Hales & Barker, 1992, 2001; Matthews, 2002). These adaptations are referred to as programming because they are thought to “set” the biological system of the organism in a manner that persists into adulthood. This adaptation occurs during a particular period in development, and in that way, the model has some similarities with the sensitive period models. However, programming models hypothesize a connection between the organism and its (early) experiences that differs from the connection in a sensitive period model.

Programming models predict variation among individuals within a species according to early exposure; therefore, individuals may vary from one another according to their early environmental experiences. In other words, the programming models attend not only to the nature of the organism (e.g., that the stress-response system is sensitive to experience in early development), but also to the variation in quality of early environmental experiences. Variation in early environmental exposure will determine an individual's "set point" and therefore influence how individuals might differ from one another in, for example, their response to a subsequent stress.

The notion that the fetus/infant *adapts* to the early environment is critical for what it says about organism-environment transactions (i.e., they are active from early in ontogeny) and for what it implies about an evolutionary influence (e.g., Crespi & Denver, 2005). The concept of adaptation reflects the view that this model is not so concerned with normal versus deviant development, but rather with the fit between the organism and its environment. So, for example, rather than view the programming of the hypothalamic-pituitary-adrenal (HPA) axis in the fetus or infant as a sign of vulnerability or pathology, it may be more appropriate to view the adaptation that is made as a signal of the organism's preparedness for its (later) environment. Thus, mothers who experience increased stress in pregnancy may be signaling to the offspring that a more responsive stress response may be adaptive for its particular environment. The possibility that there may be costs associated with certain kinds of adaptations is inherently context-dependent; that is, these adaptations can be judged only in relation to the organism's subsequent environment. This concern for the organism's environment later in development, after the "ontogenetic vulnerability," provides a further conceptual contrast between the sensitive period and programming models. Thus, adaptation or programming can be conceptually distinguished from sensitive period models—although the two may be difficult to distinguish empirically.

The concept of programming has been applied to several contexts. One widely replicated example is prenatal stress in animals. Many research teams have shown that exposing pregnant animals to uncontrollable mild stress programs the fetus's HPA axis to be stress-(over)responsive, and that this disposition is carried into adulthood and leads to a range of biobehavioral outcomes (Henry, Kabbaj, Simon, LeMoal, & Maccari, 1994). This exemplar of developmental programming is discussed in more detail later. Epidemiological investigations in humans suggest that there may be

fetal programming with respect to nutrition in pregnancy, fetal growth, and reduced glucose tolerance and cardiovascular fitness in adulthood (Barker, 1998; Eriksson et al., 1999; Hales & Barker, 1992, 2001; Lucas, 1998; Ravelli et al., 1998). That is, poor nutrition in fetal life leads to permanent alterations—adaptations—in the fetus and child; the thrifty phenotype that results may then be ill-prepared if the postnatal environment is not nutritionally poor.

Individual Differences versus Species Typical Development

Studies on developmental programming are typically concerned with differences in outcomes among a sample of individuals. Further, there is interest in linking differences among individual outcomes with variation in gradients of environmental exposure. That is shown in recent animal studies (Francis & Meaney, 2002) and human studies linking birthweight to adult risk for cardiovascular disease. Thus, in contrast to the sensitive period models, programming models tend to focus on variation within the normal and pathological range and not merely on species-atypical or grossly aberrant behaviors.

Nature of the Environmental Input

The programming model assumes a substantial role for the early environment on long-term development; indeed, it is the early environment that determines the set point for the organism—presumably within a range of species-bound set points. Thus, the impact of the early environment is substantial and lasting, and the timing of this input is essential. On the other hand, the identity of the particular environmental experience that programs the set point for the organism is not always precisely defined or determinate. So, for example, in the case of prenatal stress programming the fetal HPA axis, any of several types of environmental adversity that increase stress in the pregnant mother could serve the same programming effect.

The Role of Psychological Mechanisms and the Prominence of Human versus Animal Studies

Whereas research on sensitive periods is dominated by animal investigations, research on humans has played a key role in the popularization of the programming hypothesis. Nevertheless, the mechanism implied by the programming model is wholly biological. Several examples have been discussed involving a wide array of biological systems, such as the HPA axis, pancreatic function, and the cardiovascular system. There is no evidence yet of a psychological mecha-

nism being programmed by early experience, although there have been few attempts at this sort of research. One of the few human studies to explicitly program effects for psychological outcomes (Rutter & O'Connor & the English and Romanian Adoptees Study Team, 2004) found evidence of persisting disturbances but no clear evidence of underlying psychological mediating factors (such as cognitive development). In fact, most psychological processes are described as open to change rather than set by early experience (Bowlby, 1988; Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002).

Likelihood of Recovery or Resilience

The degree of recovery (or, more broadly, change of any sort) that can be expected following early programming is not yet clear. In the case of programming of the HPA axis, research findings lead to two important and complementary conclusions. The first is that the effects of prenatal stress are evident in adult offspring; the second is that the effect of prenatal stress may be eliminated by manipulating the early postnatal environment, through adoption or pharmacologically (Francis, Diorio, Liu, & Meaney, 1999; Ladd et al., 2000; Maccari et al., 1995). It can be asserted that an intervention delivered during the programming period would have a strong and persisting effect (e.g., to “reset” the set point). What has received far less attention is whether or not there is a point after which interventions would not effect change in the organism’s set point. There is evidence that such a point does exist, such as the peri-adolescent period, but data are limited (Barbazanges et al., 1996; Darnaudery et al., 2004).

The implications of the programming hypothesis for interventions with humans are not known. To date, human investigations have simply demonstrated that such processes may exist. Whether or not response to intervention (e.g., for cardiovascular disease) differs according to the presence of a programming origin of the disease requires further research.

Life Course or Cumulative Effects Models

Life course developmental models propose that individual differences in psychological development arise from the individual’s particular profile of risk and protective experiences as accumulated through development. The model is developmental because there is concern for when in development the individual was exposed to risk or protective factors and how they shape the trajectory or pathway that the

individual follows. The metaphor of developmental pathways (Bowlby, 1988) is helpful in illustrating, first, that the link between early adversity and later outcome is probabilistic rather than deterministic and, second, that there is a developmental order or logic in connecting early experience through to later outcomes. Several implications follow from this, including the hypothesis that early experiences predict longer-term outcomes only insofar as the effects of the early risk exposure is reinforced or maintained by subsequent events. Early risk, in the absence of concurrent risk, would be expected to have little or no effect. Thus, in contrast to the previous two models, life span developmental models view the significance of early experience in terms of subsequent exposures and experiences. Life course models seek to explain and quantify what is carried forward in development. This perspective emphasizes that early experiences are not *directly* causally linked with long-term outcomes, but are instead mediated by the risk and protective factors that follow. To a considerable extent, life span developmental models are central to much of the research on risk and resilience in psychological development (A. M. Clarke & Clarke, 2000; Schaffer, 2000).

Normative and nonnormative transitions such as the transition to early adolescence and adjustment to parental divorce attract particular attention in life course models because these are points in the developmental pathway at which a turn for the better or for the worse might be most likely and most easily assessed. It is also noteworthy, for heuristic purposes, to place the developmental stage theories of Piaget, Freud (Anna and Sigmund), Erik Erikson, among others in this category of models. Stage theories are quintessentially developmental because they propose something specific about the organism at one stage in development that is distinct from another stage (e.g., the need to resolve autonomy conflicts) and further suggest that there is a carrying forward of the effects of successes and failures of resolving these developmental tasks into the next stage. So, for instance, as Sroufe (1996) proposed, an insecure attachment in infancy may be viewed as a risk *because* it increases the likelihood of failure at subsequent stage-salient tasks, such as emotion regulation and the formation of positive peer relationships.

Individual Differences versus Species-Typical Development

Life course developmental models seek to explain variation among individuals in the developmental pathways followed and how these different developmental pathways predict individual differences in adjustment. Thus, the focus is on

variation within the normal-abnormal range. However, although the extremes on the continuum, such as serious psychopathology, are considered in research using this model, there is no presumption that the outcomes of interest are anything but species-typical behaviors. Moreover, for the most part, the kinds of environments under investigation are also within the normal range, although again, extremes of the continuum are considered, such as extreme poverty and parental maltreatment.

Nature of the Environmental Input

A focus in life span developmental research is to identify the kinds of risk experiences that are associated with individual differences in adjustment across the life span. A guiding hypothesis is that exposure to environmental risk is directly or indirectly linked with individual differences in adjustment. However, compared with previous models, life span developmental models assume a more complex, dynamic, and transactional connection between the organism and its environment. So, for example, if the goal is to predict depression in adulthood, life span developmental models would presume that any of a number of risks might play an important role, that no one risk experience is necessary or sufficient, and that, most likely, there is a complex of factors that, collectively and cumulatively (over time), predict adult depression. Related to this last point is the proposal that there is multifinality (exposure to a certain risk may lead to diverse outcomes among individuals) and equifinality (individuals may end up at the same [mal]adapted outcome by traversing different pathways or patterns of risk exposure; Cicchetti & Cohen, 1995). No such degree of flexibility between exposure and outcome is assumed in the sensitive period or programming models discussed earlier.

The Role of Psychological Mechanisms and the Prominence of Human versus Animal Studies

Whereas animal studies have been fundamental to testing sensitive period and programming hypotheses, animal studies are rarely designed to test life span developmental models. In other words, the favored model in research designs is different in animal and human research. There are a number of good and practical reasons for this. Nevertheless, an implication is that much of the research on early experience in animal studies may be difficult to translate to humans because research designs in the animal and human contexts make different presumptions about how early experience might confer risk for long-term development.

Life span models favor psychological mechanisms to explain links between early experience and longer-term out-

comes, and due consideration is also made of the larger social and historical context (e.g., Schoon et al., 2002). Comparatively few examples exist to show that psychological mechanisms mediate connections between early experience and long-term outcome. This is not so much because there is no evidence for important psychological processes in the infant and child (Fonagy, Gergely, Jurist, & Target, 2002; Jaffee, Beebe, Feldstein, Crown, & Jasnow, 2001), but rather because there are not sufficient data to show that early experiences that led to certain psychological adaptations mediate long-term adjustment. Child-parent attachment may be one possibility (Waters, Merrick, Treboux, Crowell, & Albersheim, 2000), but available data do not demonstrate that it is attachment in infancy per se that predicts long-term adjustment. On the other hand, there is ample evidence starting from around midchildhood that comparatively stable and robust psychological mechanisms, such as attributional style and cognitive-behavioral style, may mediate long-term well-being. These characteristics are not readily recognizable in the infant or young child, however. Partly for this reason and based on their finding that behavioral continuity into adulthood was robust only from the early school years, Kagan and Moss (1962/1983) suggested that the early school years may be a critical period of behavioral organization that may have lasting effects. Behavioral organization and psychological processes prior to middle school may have less persisting influence, although this question requires further direct and rigorous testing.

Likelihood of Recovery or Resilience

Life span developmental models are easily distinguished from the other models by emphasizing that there is substantial potential for recovery following early experiences or exposure to adversity. Indeed, the expectation from the risk/resilience literature, which is most amenable to the life course model, is that the individual is highly malleable, and there are comparatively few (if any) limits on whether an intervention may be applied to improve psychological well-being. In fact, the limits of resilience as it relates to when in development an intervention may be effective remain to be specified—because they are rarely made explicit. So, for example, major life events that occur later in development may be as important, and perhaps more important, as those in early life in shaping later adjustment. Empirical examples from naturalistic longitudinal studies that show dramatic change in life course pathways are provided by research on enrollment in the military (Elder, 1986) and marriage (Quinton & Rutter, 1988). Thus, life

span developmental models (implicitly) propose that the timing of the intervention is not as important as the type or intensity of the intervention.

Discredited Models

Finally, it is worth noting some proposals about development and early experience that have been discredited. First among these is the idea that development can be “arrested” or “frozen,” with the corollary that a goal of treatment is to “unfreeze” development. Currently, the application of this mistaken notion is seen in the case of children with an attachment disorder. It has been shown that children who experience extreme caregiving deprivation develop marked disturbances in attachment and social relations characterized by an apparent inability to develop selective or discriminating relationships with subsequent caregivers (see later discussion). Several authors (e.g., Howe & Fearnley, 1999; Keck & Kupecky, 1995) have proposed that because the children did not experience adequate early caregiving, including appropriate response to distress but also basic contact, features of the child’s development were arrested or frozen. Radical forms of therapy, in which the child is forced into contact with a therapist, have been proposed as a solution. The holding that is incorporated into the treatment is thought to satisfy the needs of the older child-as-infant and “bring forward” the child’s development into normality. Not surprisingly, that form of treatment has not been shown to be effective and may, in fact, exacerbate the child’s disturbances. A problem here is that the concept of regression was taken literally to mean that the 8-year-old child is, in terms of attachment development, an infant and needs to be treated as such. Such a conceptualization of regression or developmental arrest is also out of step with contemporary psychoanalytic thinking (Eagle, 1984; Gedo, 1980), on which it was very loosely based. In fact, current psychoanalytic views of disturbance brought about by failure to resolve age-salient tasks (which may nevertheless differ according to schools of thought; e.g., Eagle, 1984) are more akin to standard models that guide developmental psychopathology research (Cicchetti & Cohen, 1995).

Summary

Evidence supporting the persisting effects of early experience was previously only robustly demonstrated in experimental animal studies. That is changing, as several lines of research demonstrate surprisingly strong and persisting effects of early experience in humans. Data of that sort have become available because of the opportunities afforded by

“natural experiments” and the increasing technological sophistication available to study neuroscience phenomena. Recent reviews of ideas and data on early experience in animals and humans (Bruer, 1999; Cacioppo et al., 2002; A. M. Clarke & Clarke, 2000; Nelson & Luciana, 2001; Schaffer, 2000) suggest that no conceptual consensus has yet emerged and that there are important conceptual controversies that need clarification. It may be that each of the models just discussed have strengths and weaknesses in accounting for the accumulation of data on early experiences and long-term outcomes.

This section considered and contrasted several of the leading models of how, and if, early experience may have lasting psychological effects on the organism. This review was illustrative rather than exhaustive, both in terms of identifying models and articulating dimensions on which the models may be differentiated. Highlighting sources of conceptual and methodological leverage for testing these models is the focus of the next section.

CONCEPTUAL AND METHODOLOGICAL CONSIDERATIONS

This section examines the particular conceptual and methodological issues learned in the course of conducting research into the effects of early experiences, particularly with reference to applications in humans.

Design Strategies

Progress in understanding if and how early experiences may have persisting effects in humans is hampered by the fact that, in most circumstances, risk exposure is not precisely timed or restricted to a particular period in development. On the contrary, most environmental risks of conceptual or public health interest are continuous. Therefore, whether the risk is poverty, child maltreatment, or parental mental illness, children are exposed to persisting psychosocial risk, and so it is difficult to disentangle the effects of early experiences per se from the cumulative effects of continuous adversity. Complicating this situation further is the fact that the most important risks do not exist in isolation, and exposure to one kind of risk may increase the likelihood of exposure to additional and subsequent risks. For instance, poor parenting in infancy and early childhood is likely to be stable from childhood to adulthood, covary with social and economic risks (marital conflict, economic strain), and lead to poor peer relationships and exposure to deviant peers. Analytic strategies may be employed to

account for these co-occurring risks, but demonstrating that there is an independent effect of one particular risk on outcome when others are covaried may not carry much weight if the nature of the risks is to covary in development. Thus, even in multivariate analyses, there may be dangers in drawing direct causal connections between any particular risk experienced at a particular point in development and psychological disturbance. Evidence of the complex interdependence of risks for compromised psychological development is one of the more important practical lessons from naturalistic studies of child development.

In contrast to naturalistic studies that dominate human research, animal studies make good use of experimental designs in which a particular early experience is randomly assigned to animals in different groups and the outcomes of the two groups are later compared. Experimental designs naturally afford greater security against undetected or unmeasured bias, although the generalizability and ecological validity of the findings may be threatened to the extent that excessive experimental control is introduced.

Experimentally introducing early stress in human studies in a way that resembles the experimental animal literature would not, of course, be ethical. However, “experiments in nature” (Bronfenbrenner, 1979) exist that might provide some leverage in testing hypotheses about early experiences in humans. Natural experiments are naturally arising conditions in which there is a possibility of separating otherwise confounded processes, or they provide opportunities to test developmental hypotheses that would not be possible because of ethical or practical reasons. Several natural experiments exist in the literature on early experiences, including studies of children who were rescued from institutional deprivation (Chisholm, 1998; Gunnar, Morison, Chisholm, & Schuder, 2001; O’Connor, Rutter, & the English and Romanian Adoptees Study Team, 2000), follow-up studies of adults whose mother experienced prenatal famine induced by war (Brown et al., 2000; Ravelli et al., 1998), and studies that examined the effects of specific stresses that were outside of the control of the subjects, such as an ice storm (Laplante et al., 2004) and an earthquake (Glynn, Wadhwa, Dunkel-Schetter, Chicx-Demet, & Sandman, 2001). Findings from these experiments in nature have provided critical data for documenting the persisting effects of early experiences in humans.

To the extent that “typical” experimental control is possible in human studies, it comes in the form of intervention or prevention trials. Many experimental intervention studies have targeted early experience, although comparatively few directly test the timing hypotheses that underlie the conceptual models reviewed earlier. Because of the impor-

tance of these studies they are considered separately in the final section.

Timing, Frequency, and Severity of Exposure and Ontogenetic Patterns

For most psychological outcomes of interest we do not have enough information to determine what the window of sensitivity is—if one exists at all. One strategy for identifying such periods is to base developmental investigation on what is known about the sharp periods of discontinuity in brain development. This has been shown most clearly in the area of cognitive development (Herschkowitz, Kagan, & Zilles, 1997; Huttenlocher, 1994); on the other hand, application to social outcomes is elusive. This is a strategy borrowed from the sensitive period model: Environmental input may be most important during periods of dramatic biological change, notably brain development. In other words, knowledge of ontogeny should shape the study of environmental experience and exposure.

Teicher et al.’s (2003; see also, Anderson, 2003) summary of the preclinical data suggested that there may be specific features of those brain regions that may be particularly vulnerable to early stressful experience. Characteristic features are thought to include a protracted postnatal development, including postnatal neurogenesis and a high density of glucocorticoid receptors. So, for example, research into the brain bases of persisting early effects might profitably target brain areas with these features. Additional strategic insight is being generated by genetic research on ontogenetic development. One recent example concerns the ontogeny of the glucocorticoid receptor gene and its expression in brain development (Speirs, Seckl, & Brown, 2004). Results from this type of investigation suggest which areas of the brain at which points in development may be most relevant to study the effects of early stress.

Translating ontogenetic findings into practical results will, by design, depend on the type of environmental experience and the mechanism involved. A strong example of an environmental effect (albeit in utero) being informed by ontogenetic development was reported by Hansen and colleagues (Hansen, Lou, & Olsen, 2000). They found that severe life events experienced in the first trimester of pregnancy increased the risk of congenital abnormalities in neural crest-derived organs in the fetus/child. The finding that the effect for this outcome was for the first trimester only is significant given that this is when gross organ formation would be most vulnerable. Somewhat comparable findings were reported by other investigators (e.g., Nimby, Lundberg, Sveger, & McNeil, 1999). On the other hand, re-

search on prenatal stress/anxiety in relation to behavioral/emotional outcomes has produced inconsistencies as regards timing of stress in pregnancy. Thus, whereas some studies suggest that stress/anxiety in midpregnancy may be most predictive (Van den Bergh & Marcoen, 2004), others emphasize late pregnancy (O'Connor, Heron, Golding, Beveridge, & Glover, 2002). There may be methodological and practical reasons for these inconsistencies, such as the difficulty in timing anxiety or stress precisely; there may be biological explanations as well, as several kinds of effects on the developing brain at different points in development may yield similar-looking effects on, for example, attention and broad behavioral phenotypes. In any event, it is not clear how to reconcile these contrasting findings and synthesize them with experimental data suggesting that midgestation is the point after which the human fetus can mount its own (independent) stress response (Gitau, Fisk, Teixeira, Cameron, & Glover, 2001). In this case, knowledge of ontogenetic development is no guarantee that the nature of the environmental effect or the putative mechanism will be revealed.

Child-parent attachment is another area of study in which an ontogenetic model of the formation of discriminating attachments has been tested (Bowlby, 1982). Given the conceptual and empirical work in this area, it might be expected that the timing of the onset of caregiving deprivation may result in differential disturbances, and there is some evidence for this (Vorría, Rutter, Pickles, Wolkind, & Hobsbaum, 1998; Wolkind, 1974). For example, Wolkind found that disinhibition toward strangers was uniquely associated with *early* institutional care but not institutional care that occurred postinfancy, that is, past the point that the child formed a selective or discriminating attachment relationship with the caregiver. On the other hand, studies of child-parent attachment following early caregiving deprivation that started at or immediately following birth and continued into the early months and years of life find less distinct or qualitative differences in outcomes according to age at adoption (e.g., O'Connor et al., 2003). In fact, the finding that both early-placed children as well as later-placed children exhibit the same form of severe disturbance has raised some important ontogenetic and etiological questions.

There are different timing of measurement implications for testing life span models of early risk on later development. Specifically, each junction hypothesized along the risk trajectory (Quinton, Pickles, Maughan, & Rutter, 1993) requires assessment. Complementing the need to time assessments according to stage-salient issues and competencies is the view that the order of major life transi-

tions (e.g., educational attainment, marriage, childbearing) should be considered. In support of this proposal are data suggesting that off-time transitions or transitions that do not follow a normative course may increase the risk for compromised long-term development (Rindfuss, Swicegood, & Rosenfeld, 1987). Whether it is the timing or the order of major events (or both), life course developmental models require a measurement-intensive approach to determine if the effects of early experience are mediated by later experience.

Questions about measurement intensity also arise in discussions of the so-called sleeper effect model, which is usually defined as the existence of a time lag between exposure to adversity and the detection of a putative effect. The possibility of sleeper effects has been raised in several developmental studies (e.g., Kagan & Moss, 1962/1983). Wallerstein (1985) proposed a similar process in suggesting that divorce in childhood may have not only immediate effects, but also effects at a later point in development, such as adolescence, when there is a rekindling of the early developmental struggle or vulnerability. The major problem with this model is largely one of measurement, as it can be supported only if it can be shown that there was no intervening effect mediating the link between exposure to early adversity and some later-detected outcome.

Individual Differences

The existence of individual differences in response to adverse environments, even gross deprivation, is often unaccounted for. This is so in the animal literature (S. L. Ramey & Sackett, 2000), notwithstanding the generally small samples included in research. Individual differences have proved to be substantial in studies following up children who experienced severe early deprivation. For example, despite more than 2 years in extreme institutional deprivation, children adopted following institutional deprivation had cognitive abilities ranging from severe delay to well above average by age 6 years of age (O'Connor et al., 2000), a pattern that continued in further follow-up assessments at age 11 years (O'Connor, 2003).

Human studies also show that there are differences among individuals in the kinds of disturbances that may result from early deprivation. Thus, whereas some children exhibit largely cognitive difficulties, others show primarily social deficits; a minority show a combination of deficits (Rutter, Kreppner, O'Connor, & the English and Romanian Adoptees [ERA] Study Team, 2001). In the ERA study, it could not be determined why institutional deprivation led to some children exhibiting quasi-autistic behavior but to

others exhibiting inattention/overactivity or attachment disturbances. It cannot be ruled out that differences in the type of disturbance exhibited are accounted for by unmeasured differences in experiences in the institution or to unmeasured biological vulnerabilities that may or may not be partly genetic in nature. Modest differences among institutions in the level of deprivation did exist. This has been shown to account for only modest variation in cognitive ability at earlier assessments (Castle et al., 1999), but leaves unexplained most of the variability observed.

Further research into the sources of individual differences associated with early exposure to stress/adversity therefore needs to consider multiple outcomes to evaluate whether some children who seem resilient on some outcomes are nevertheless vulnerable on other indices of adjustment. Furthermore, subsequent research needs to account for the near certainty that there will be domain-specific patterns across outcomes; models developed to account for language acquisition may be irrelevant for understanding variation in, for example, attachment relationships.

Sex Differences

Sex differences in response to stress, sometimes compounded by age, are well documented and are observed at several levels of analysis, from stress reactivity (Gallucci et al., 1993; Kirschbaum, Wust, & Hallhammer, 1992), to response to early adversity and potentially genetically mediated responses (Barr, Newman, Schwandt, et al., 2004), to bona fide psychological disorder (Kessler, 2003). Indeed, human studies routinely consider and find evidence for sex differences in outcomes associated with risks such as parental divorce and remarriage (Hetherington, Bridges, & Insabella, 1998) trauma (Breslau, Peterson, Poisson, Schultz, & Lucia, 2004), and broader psychosocial risks (Werner, 1989). Given the robust sex differences across species on outcomes and mechanisms that are relevant to the development of psychopathology, it is no wonder that sex is a common moderator in studies of early experience.

Finding sex differences does not lead directly or necessarily to a mechanism. The reason is that sex (i.e., biologically based differences) and gender (i.e., socially based differences) are proxies for a range of hormonal, social, and cognitive differences that are often difficult to disentangle. Each of several aspects of sex or gender could underlie mean differences in rates of disturbance following exposure to early risk or more qualitative differences in the types of effects that are observed.

On the other hand, there are noteworthy failures to find sex differences in studies of early stress exposure. Studies

of children adopted following institutional deprivation have found no or inconsistent sex differences, including on those outcomes for which there are strong sex differences, such as inattention and hyperactivity (Kreppner, O'Connor, Rutter, & the English and Romanian Adoptees Study Team et al., 2001). Indeed, in Kreppner et al.'s study, early institutional deprivation was associated with the absence of the expected sex difference. It seems unlikely that any sweeping proposal concerning sex differences in response to early stress exposure will fit the data. To the extent that sex differences are hypothesized, they need to be bound by age of assessment, outcome investigated, and proposed mechanism.

Animal and Human Models

A further obstacle to the synthesis of a model to account for early experience concerns generalizability across species. Berardi et al. (2000) and S. L. Ramey and Sackett (2000), among others, point out that demonstrations of sensitive periods are not as clear in primates as they are in birds and other species. S. L. Ramey and Sackett further note that differences between nonprimates and primates is clearly evident for socialization outcomes.

Several reasons exist for why there may not be generalizability across species. The task of translating findings from animal studies to the human context is complicated by several specific challenges, and these challenges may vary according to the risk being assessed. For example, in the particular area of prenatal stress, the threats to generalizability include (1) the varying maturity of the offspring at birth (e.g., between rats, sheep, and primates; Matthews, 2001); (2) the possible role of litter size on outcomes (Huot, Gonzalez, Ladd, Thrivikraman, & Plotsky, 2004); (3) the ease with which corticosterone crosses the placenta in the rodent compared with the protection provided against cortisol transfer in human and nonhuman primates associated with 11 β -hydroxysteroid dehydrogenase (11 β -HSD; Chailis, Matthews, Van Meir, & Ramirez, 1995; Kajantie et al., 2003; Petraglia et al., 1990); (4) the differential distribution and likely differential functional significance of receptors involved in regulating stress in rodents and primates (Sanchez, Ladd, & Plotsky, 2001); and (5) differences in brain size at birth between monkeys and humans (60% of adult versus 24%, respectively; Coe et al., 2003), which confound comparisons between nonhuman primates and humans concerning the degree of resilience in brain development following early stress exposure.

Compounding these problems in generalizing across species are clear demonstrations of nongeneralizability within species. One such difference is found in attachment

behavior in Old and New World monkeys (Suomi, 1999). But perhaps the most well-known example of this sort involves monogamous prairie voles and nonmonogamous montane voles whose behavioral differences in social and attachment behavior have been linked with differences in oxytocin and vasopressin receptor function in the brain (Insel, 1997; Young, Wang, & Insel, 1998).

Additionally, experimental animal research is based on precisely timed stressful manipulations that can be controlled in terms of duration, frequency, and intensity. Exposure to well-defined, precisely timed stressors is not representative of the kinds of even severe stresses that constitute the most significant risk phenotypes in humans. Accordingly, improving the applicability of animal findings to humans may depend on revising experimental paradigms to rely less on studies that induce extreme conditions such as deprivation and instead examine risks that are more obviously within the range of species-typical experiences. Several examples of this sort have been proposed. One paradigm used in several nonhuman primate studies is referred to as variable foraging demand (VFD; Rosenblum & Paullly, 1984). In contrast to low foraging demand conditions, in which food is made available, and high foraging demand, in which the animal needs to search and dig for food, animals in the VFD condition do not have a predictable regimen. Several studies show that offspring of mothers in the VFD condition exhibit a range of behavioral problems that may be analogous to anxiety (Coplan et al., 1996); infants whose mothers were exposed to the VFD show a wide range of neurochemical abnormalities, including elevations in corticotropin-releasing factor, somatostatin, and metabolites of serotonin and dopamine (Coplan et al., 1998). Also in primates, Maestripieri (1999) has examined another naturally occurring adverse experience, maltreatment. The fact that this exists in nature and does not require experimental manipulation or contrived circumstances has presumed benefits for generalization, both for primates and potentially for humans. Similar efforts to examine the long-term effects of naturally occurring variation are also found in rat models (Caldji, Diorio, & Meaney, 2000). It will be important to establish if findings from these more naturalistic paradigms contrast with or confirm findings using less ecologically valid paradigms. Whether or not these efforts signal a move away from extreme experimental manipulations remains to be seen.

Candidate Mechanisms

A short list of candidate mechanisms emerged to account for the persisting effects of early experience and exposure

on psychological development. In the areas of prenatal stress and caregiving deprivation there is considerable interest in an HPA-mediated mechanism (Gunnar, 2003). There are several reasons the study of early experience in humans, such as prenatal and early stresses, has focused on the HPA axis. These include the considerable animal data suggesting a programming mechanism, the documented role of HPA axis dysfunction in a range of psychological disturbances in children and adults, and emerging data from several laboratories that the effects of stress exposure can be seen in HPA axis activity. In addition, assessing HPA axis activity from salivary cortisol is comparatively easy and inexpensive. Accordingly, although basic questions remain about cortisol collection and analysis, it is one of the leading candidate mechanisms in human studies of early experience. Prospective longitudinal data on sufficiently large samples supporting the role of the HPA axis in mediating the persisting effect of early adverse exposure are still rare. However, several kinds of follow-back studies and other designs have been done (e.g., Heim et al., 2000), and this remains an active area of research.

More recent research considered genetic mechanisms, particularly those associated with neurotransmitters thought to underlie major mental illness. One study in mice (Ansorge, Zhou, Lira, Hen, & Gingrich, 2004) found that pharmacologically inhibiting serotonin transporter expression in early development with fluoxetine was associated with abnormal behavior that resembles animal models of anxiety and depression. The pharmacological intervention effect, which was found only in those animals that did not have the genetic variant of the serotonin transporter associated with reduced activity, demonstrated that altering serotonin expression for a restricted period in early development has long-term effects. The implications for use of selective serotonin reuptake inhibitors in pregnancy (for the fetus) and with young children are substantial and require follow up. Extant studies in humans are too limited in scope and length of follow-up to determine if a similar process may be operating.

Other research examined genetic moderation of the effects of early stress or deprivation. Barr, Newman, Lindell, and colleagues (2004) considered how the effects of deprivation on alcohol consumption in a nonhuman primate model would be moderated by genetic risk. They found that the effects of early deprivation were limited to those animals at genetic risk (in this case, also involving the serotonin transporter). Gene-environment interactions involving the serotonin transporter for aggressive outcomes have been reported in both nonhuman primates (Suomi, 2003) and humans (Caspi et al., 2002). In the Dunedin

study reported by Caspi and colleagues, the environmental risk was maltreatment. Given the apparent consistency of the genetic moderation effect, whereby the environmental risk exposure is observed for those at genetic risk but not for those not at genetic risk, it might well be anticipated that future research into early experiences will include genetic factors as possible modifiers of effects.

The move toward multivariate models of candidate mechanisms, such as genotype-environment interactions, may prove more directly valuable to updating conceptual models and informing clinical and preclinical human studies because they more closely resemble the context in which human research is necessarily conducted, namely, a risk context in which there are multiple competing risks operating.

Summary

Recent reports illustrate several lines of evidence of increasing conceptual and methodological leverage for testing hypotheses concerning the persisting effects of early experiences on psychological outcomes, including diversity of research designs (especially those with ecological validity) and increasing sophistication in identifying and measuring potential mechanisms. Research into the effects of how early environments shape long-term psychological development has increased dramatically in recent years, and will likely continue, as the relevance of the animal data becomes greater and more widely appreciated and the technological sophistication for studying mechanisms in humans is advanced.

EMPIRICAL ILLUSTRATIONS

Two of the most widely used paradigms for studying the persisting effects of early experience in animals are prenatal stress and deprivation in the early postnatal period. Findings from experiments of this sort provide some of the most important and compelling findings to suggest that early experiences/exposures do have robust causal and lasting effects on cognitive, social, and behavioral development, as well as on a variety of other physical and health outcomes. Research using these paradigms is comparatively rare in humans. In the case of prenatal stress/anxiety, several human studies have emerged in recent years and, although these studies vary widely in terms of sample size, length of follow-up, and measurement strategy, they offer a reliable check on the relevance of the animal studies to humans. In the case of deprivation, there are obvious ethical reasons such research can-

not be planned; however, the increase in international adoption, often involving children who experienced severe deprivation prior to placement, provides a natural experiment to examine if there are persisting effects of early adversity in the absence of current adversity. This section donates considerable attention to research using the prenatal stress and early deprivation paradigms because these are dominant paradigms in animal studies and because of the availability of human data.

Prenatal Stress/Anxiety and Fetal and Child Development

Over 60 years ago, Sontag (1941) suggested that a mother's psychological well-being in pregnancy was important for the healthy development of the fetus. That proposal was not based on available empirical data, but it did reflect a widespread belief found in many cultures dating back many centuries. It was not until many decades later that adequate empirical data were available in humans to evaluate Sontag's hypothesis.

A biological-conceptual model explaining why prenatal exposure to anxiety/stress might lead to lasting disturbances in offspring has been discussed by many authors (Glover & O'Connor, in press; Huizink, Mulder, & Buitlaar, 2004; Maccari et al., 2003; Matthews, 2002; Schneider & Moore, 2000; Wadhwa, Dunkel-Schetter, Chicz-DeMet, Porto, & Sandman, 1996; Weinstock, 2001). In brief, the model states that an increase in anxiety/stress in pregnancy accentuates activation of the maternal HPA axis, leading ultimately to a release of cortisol (corticosterone in rodents); furthermore, the maternal cortisol released is not fully metabolized by the placenta and crosses to the fetus, where it influences the developing fetal HPA axis and, more broadly, fetal brain development. There are many other important features of this model. One is that the placenta has a major but not yet fully understood role in this process. For example, the placenta acts as a protective barrier against the transfer of maternal cortisol to the fetus via the enzyme 11 β -HSD. Significantly, however, although estimates vary about the extent to which maternal cortisol may be metabolized, available data indicate that there is significant maternal-fetal cortisol transfer, with a correlation in one study of $r = .58$ (Gitau, Cameron, Fisk, & Glover, 1998). There is also evidence for a substantial correlation between maternal and fetal plasma levels of corticotropin-releasing hormone (Gitau, Fisk, & Glover, 2004) and testosterone (Gitau, Adams, Fisk, & Glover, 2004); on the other hand, no evidence of maternal-fetal transfer was observed for noradrenaline (Giannakouloupoulos, Teixeira, Fisk, & Glover, 1999). These data suggest that

there is maternal-fetal transfer, at least for several important substances, and therefore provide a useful basis for hypothesizing how maternal psychological states and their hormonal accompaniments may influence fetal and child development.

Another aspect of the model, yet to be adequately tested in humans, is that the developing fetal HPA axis is especially vulnerable to input during this period, although the boundaries that define this period of sensitivity are not certain and may include postnatal development. An additional component of the model is that this process operates in the context of the dramatic normative increase in maternal cortisol from mid- to late pregnancy, the causes and implications of which are not fully understood. Thus, elevated levels of glucocorticoids are regarded as a potential risk for child and obstetric outcomes, not least of which is premature birth (Wadhwa, Sandman, & Garite, 2001). However, even if there are adverse effects in some situations, it is equally clear that glucocorticoids serve important biological functions, such as preventing/reducing respiratory distress syndrome in children at risk of being born premature (e.g., MacArthur, Howie, Dezoete, & Elkins, 1981). The trick has been to find meaningful individual differences in maternal cortisol during pregnancy, a time of considerable normative increase, and relate this to fetal/child outcomes. That is the missing piece of the research puzzle, at least in humans.

As a result of this increased sensitivity or vulnerability to environmental input in early development, the HPA axis in the offspring may be set or programmed in early life. That, at least, is the conclusion of several authors based on the animal research reviewed next. Furthermore, an essential application of the model is that, because cortisol is involved in numerous biological systems, the effects of increased cortisol would have nonspecific effects on the offspring. These nonspecific effects arise from the putatively direct involvement of HPA axis activity in, for example, cognitive function (Lemaire, Koehl, LeMoal, & Abrous, 2000), stress response to threat (Griffin, Skinner, Salm, & Birkle, 2003; Ward, Johnson, Salm, & Birkle, 2000), and immune function (Coe, Kramer, Kirschbaum, Netter, & Fuchs, 2002; Coe & Lubach, 2001; Kay, Tarcic, Poltyrev, & Weinstock, 1998; Sobrian, Vaughn, Bloch, & Burton, 1992), as well as from the indirect involvement of the HPA system in the opioid and catecholamine systems (Insel, Kinsley, Mann, & Bridges, 1990; Peters, 1988).

Animal Findings

The model just described is based on, and is the basis for, extensive experimental animal research. Convergent find-

ings from animal studies link stress experienced by the mother during pregnancy with impaired adjustment in the offspring. This is a remarkably robust finding that has been reported in many labs in several countries and dates back decades (Ader & Belfer, 1962; Thompson, 1957). Behavioral/emotional disturbances most likely to be affected include attentional problems, anxiety/withdrawal, motor impairments, sleep dysregulation, and increased behavioral response to stress (Alonso, Navarro, Santana, & Rodriguez, 1997; Lehmann, Stohr, & Feldon, 2000; Schneider, Coe, & Lubach, 1992; Williams, Hennessy, & Davis, 1995). As noted earlier, neurodevelopmental and biological levels of analysis provide an equally compelling set of adverse outcomes, with the primary disturbances being an enhanced physiological reactivity to stress paradigms, impairments in immune functioning, compromised neurogenesis particularly in the hippocampus, and poor cardiovascular outcomes, among others (Baum, Ortiz, & Quan, 2003; Biagini & Pich, 2002; A. S. Clarke, Wittwer, Abbott, & Schneider, 1994; Dodic, Abouantoun, O'Connor, Wintour, & Moritz, 2002; Edwards, Dortok, Tam, Won, & Burnham, 2002; Henry et al., 1994; Schneider et al., 1998; Szurman, Pliska, Pokorby, & Welzl, 2000).

Much of this work implicates changes in the HPA axis as one of several potential mechanisms mediating this link (Maccari et al., 2003; Schneider & Moore, 2000; Weinstock, 2001). This is supported by the finding that mimicking the physiological effects of stress by injection of adrenocorticotropin hormone (in nonstressed pregnant animals) has the same effect as exposing pregnant mothers to uncontrollable environmental stress (Schneider et al., 1992).

Collectively, evidence from experimental manipulations in these studies implies that prenatal stress *causes* adverse outcomes. Given the strength of these findings, it is surprising that large-scale systematic research in this area has been conducted only in the past 5 years.

Human Studies of Prenatal Stress/Anxiety

In humans, there is strong evidence that prenatal maternal anxiety/stress is associated with *fetal* behavior (DiPietro, Costigan, & Gurewitsch, 2003; DiPietro, Hilton, Hawkins, Costigan, & Pressman, 2002; Monk et al., 2000; Monk, Myers, Sloan, Ellman, & Fifer, 2003; Sandman et al., 2003). These studies show that, for example, fetal behavior (e.g., activity level) and heart rate are associated with maternal anxiety/stress, measured either as a state or trait characteristic or when induced experimentally. Specifically, DiPietro, Hodgson, Costigan, and Johnson (1996) reported that greater perceived stress in pregnant women was associated with reduced fetal heart rate variability; that

may be significant insofar as heart rate variability may increase the likelihood for or be a marker of temperamental behavioral inhibition.

There is also extensive support for a link between prenatal maternal stress/anxiety and obstetric outcome (Copper et al., 1996; Hedegaard, Henriksen, Sabroe, & Secher, 1993; Wadhwa, Sandman, Porto, Dunkel-Schetter, & Garite, 1993), possibly via an HPA-mediated mechanism (Wadhwa, Porto, Garite, Chicz-DeMet, & Sandman, 1998). In the large ($N = 8,719$) Danish study reported by Hedegaard et al., maternal self-reported general distress at 30 weeks gestation predicted an increased risk of preterm delivery, defined as less than 37 weeks. A conclusion from these studies is that maternal life stress or anxiety is associated with a clinically significant reduction in birthweight and/or gestational age at delivery. What is not clear from these studies is whether the increased risk of poor obstetric outcome is associated with longer-term effects on the child.

Evidence supporting a direct link between prenatal maternal anxiety/stress and child development is limited but growing. Perhaps the earliest study to examine the issue in humans was reported by Stott (1973). In a sample of approximately 200 women, Stott found that maternal stresses reported during pregnancy predicted offspring poor health and behavioral development in early childhood. Other studies also addressed this issue, but suffered from one or other important methodological limitation, such as failure to distinguish pre- from postnatal stress or reliance on retrospective report. Nevertheless, some of the results deserve attention. For example, in a subsample of approximately 700 children in the Oregon Adolescent Development Project, Allen and colleagues (Allen, Lewinsohn, & Seeley, 1998) found an association (odds ratios of 2 or more) between retrospectively reported maternal emotional health and diagnosed anxiety, depression, disruptive behavior, and substance use disorder in the child at midadolescence; the link with disruptive behavior persisted after multiple covariates were included, such as numerous indicators of current risk.

Several prospective, longitudinal studies of prenatal maternal anxiety or stress that have been reported in recent years suggest (1) that there is a dose-response association between maternal prenatal distress and child outcomes; (2) that the effects pertain to behavioral/emotional development and problems, cognitive development, and neurological development; (3) and that the effects persist into childhood and perhaps early adolescence. To a considerable extent, then, these findings paint a surprisingly similar picture to the one drawn from animal findings.

Results from the Avon Longitudinal Study of Parents and Children (ALSPAC), a prospective longitudinal study of women living in southwest England, provide some of the strongest evidence to date that maternal prenatal stress/anxiety predicts behavioral/emotional problems in the child. Specifically, mothers who reported high levels of anxiety in late pregnancy had an approximately twofold increased risk of children with significantly elevated behavioral/emotional problems at 47 months, even after other prenatal, obstetric, and psychosocial risks and *postnatal* anxiety and depression were statistically accounted for (O'Connor et al., 2002). Follow-up of the children to 81 months indicated that the effect of prenatal anxiety not only remained significant, but was of comparable magnitude to what was found earlier (O'Connor, Heron, Golding, Glover, & the ALSPAC Study Team, 2003). More recent data, based on a subsample of approximately 70 children at age 10½ years, indicated that prenatal maternal anxiety predicted children's diurnal salivary cortisol, with significant effects obtained from morning and afternoon levels (O'Connor et al., 2005). Data of this kind are needed to establish the HPA axis as a mediating mechanism in humans.

In their longitudinal study of 72 families in Belgium, Van den Bergh and Marcoen (2004) reported modest to moderate links between prenatal maternal anxiety assessed between 12 and 22 weeks gestation and cross-informant composite measures of attention and externalizing and self-reported anxiety in 8- to 9-year-old children; these effects were obtained after accounting for key covariates, such as smoking in pregnancy and socioeconomic status, and postnatal anxiety. Results from these studies have been replicated, to a surprising degree, in large-scale studies (e.g., Rodriguez & Bohlin, 2005). In younger children, several groups (Buitelaar, 2003; Huizink, de Medina, Mulder, Visser, & Buitelaar, 2002; Susman, Schmeelk, Ponirakis, & Garipey, 2001) reported links between prenatal maternal anxiety and temperament in the child, thus carrying on the research predicting fetal behavior and likely anticipating the behavioral/emotional problem outcomes reported in the longer-term follow-up studies. Although the data so far reported suggest that prenatal maternal anxiety or stress is associated with a broad range of behavioral/emotional problems in children, there is a consistent tendency among studies to find that predictions of attentional problems are particularly strong. What that means is not yet clear, and there may be a number of explanations involving attention, memory, and other brain regions and systems. Longer-term follow-up periods into adolescence are necessary to ascertain if the effect carries over to bona fide depression,

which is rare prior to adolescence but is the phenotype most closely linked with HPA axis dysregulation. In this regard, a recently reported finding from Murray and colleagues (Halligan, Herbert, Goodyer, & Murray, 2004) on their follow-up study of children of mothers who experienced postnatal depression may be significant. They found that 13-year-olds exposed to postnatal maternal depression exhibited elevated levels of morning cortisol, a pattern also found in depressed adolescents. The risk involved (at least) *postnatal* depression, but the study is suggestive in showing that early experience may confer long-term risk by altering HPA axis functioning.

Complementing the data on behavioral/emotional outcomes are several studies that assess cognitive and language outcomes in children. A Montreal study found that prenatal maternal stress associated with a severe ice storm accounted for modest but significant variation in children's mental and language development scores in infancy (Laplante et al., 2004). Comparable associations, although based on different measures of stress/anxiety and outcome, were reported in other studies (Brouwers, van Baar, & Pop, 2001; Huizink et al., 2002). Field and colleagues (2003) found that maternal anxiety in pregnancy was associated with children's greater relative right frontal EEG activation and lower vagal tone; associations were also reported with sleep and scores on the Brazelton neonatal scale.

Still other research shows that an important aspect of neurodevelopment, atypical laterality, is linked with maternal prenatal anxiety. In the ALSPAC sample, Glover, O'Connor, Heron, and Golding (2004) reported that maternal prenatal anxiety at 18 weeks gestation was associated with a 23% increase in the child showing mixed handedness, independent of parental handedness and obstetric and other antenatal risks. Remarkably consistent with those findings were results reported by Obel, Hedegaard, Henriksen, Secher, and Olsen (2003) in a Danish study of 824 women who were assessed prospectively from pregnancy. Data from the Glover et al. and Obel et al. analyses are similar in several respects, including the prediction to mixed handedness (rather than, e.g., left handedness) and the link with anxiety rather than depression (despite different measures used in each study), although they differed on when in pregnancy anxiety was most strongly linked with outcome.

Multiple mechanisms may account for a link between maternal anxiety/stress in pregnancy and poorer obstetric and child behavioral and cognitive outcomes. Hypothesized mechanisms involving HPA axis activity are dominant, but alternative or complementary mechanisms may be at work.

Among the more likely candidates is testosterone. Experimental animal research demonstrates that fetal testosterone programs the male fetal brain for its masculine role (Goy & McEwen, 1980). Human data also suggest that testosterone exposure in utero may have lasting effects. So, for example, girls with congenital adrenal hyperplasia, who have a deficiency of cortisol but an excess of testosterone, exhibit a higher level of rough-and-tumble play, greater likelihood of choosing masculine toys in play (Berenbaum & Hines, 1992; Hines, Golombok, Rust, Johnston, & Golding, 2002), and altered laterality (Nass et al., 1987). It is interesting to note that treatment for congenital adrenal hyperplasia is prenatal dexamethasone, a glucocorticoid (Meyer-Bahlburg et al., 2004). Prenatal maternal stress, which may raise fetal cortisol level, may also cause an increase in testosterone level, a mechanism that may explain a link with several outcomes associated with prenatal stress, such as mixed handedness, Attention-Deficit/Hyperactivity Disorder, and learning disabilities. Still other mechanisms may be at play, including the opioid system (Insel, 1990). Furthermore, in a normal population Sjöström, Valentin, Thelin, and Marsal (1997) found that in the third trimester, fetuses of women with high trait anxiety scores had reduced blood flow in the umbilical artery and in the fetal middle cerebral artery. Comparable findings were reported by Teixeira, Fisk, and Glover (1999). The implication of this research is that, although involvement of the HPA axis seems very likely, there are a range of alternative and complementary mechanisms that also require further study.

Early Maternal Deprivation and Subsequent Child Attachment and Social Relationships

Maternal or caregiving deprivation is the second paradigm to study early experiences and their persisting effects. As in the case of prenatal stress, much of the information derives from animal experiments, such as the work of Harlow and colleagues (1969, 1970), although in this case, the impetus for much of the animal work was the early clinical observations of humans by Bowlby (1951), Spitz (1946), and others.

Animal Studies

It has been appreciated in the animal research literature for many years that the quality of early caregiving has immediate and lasting effects on the offspring (Harlow & Suomi, 1970; S. L. Ramey & Sackett, 2000; Sackett, 1965; Suomi,

1999). Recent animal studies have made considerable progress in understanding the neurophysiological basis of these early experiences on brain development, including the possibility that these alterations may serve to transmit risk to subsequent generations (Caldji et al., 2000; Champagne & Meaney, 2001; Francis, Champagne, & Meaney, 2000; Kraemer & Clarke, 1996; Weaver et al., 2004).

The elegant work of Cameron (2004) shows a clear timing effect of caregiving deprivation. In her studies, rhesus monkeys were placed in a social group with other monkeys. Baby monkeys were then separated from their mother: One group experienced separation at 1 week, another group at 1 month, a third group at 3 months, and a final group experienced separation at 6 months of age. Monkeys were provided adequate nutrition and received adequate physical care, and so it could be inferred that subsequent group differences that were observed were due to the timing of maternal separation. Behavioral observations of the monkeys in the four distinct groups were recorded in several settings, and accounts were made of several types of behavior, including affective and affiliative behaviors and response to threat. Findings indicated that, across a range of behaviors and settings, consistent differences emerged, with monkeys who experienced early separation showing generally less competent, more distressed behavior. Biological differences were also observed that may underlie these behavioral differences, including neuronal development in the prefrontal cortex and gene expression in the amygdala.

Particularly interesting from Cameron's (2004) studies was the finding that monkeys separated at 1 week were different in kind from other monkeys, including those separated at 1 month. Whereas monkeys who experienced separation at 1 month showed modest behavioral abnormalities (e.g., excessive clinging) compared with the monkeys in the later-separated groups, monkeys experiencing separation at 1 week exhibited flagrantly more disturbed and abnormal behavior that was not observed in any other group. Monkeys separated at 1 week were especially distinguishable from monkeys in all other groups on several indicators, particularly involving seeking comfort. For example, only those monkeys who experienced maternal separation at 1 week showed little interest in seeking out others for comfort or protection. The meaning of and motivation for attachment and social behavior in these 1-week separated monkeys, when such opportunities were later observed, was clearly different from that in monkeys who experienced separation later in development. Arguably, these monkeys did not develop a selective attachment relationship with the mother, which is the foundation for attach-

ment. This is an intriguing explanation for the divergent behavioral effects because a strikingly similar pattern has been noted in a minority of children who experienced early severe and prolonged institutional deprivation and did not form early selective or discriminating attachments (O'Connor, Marvin, et al., 2003; Zeanah, Smyke, & Dumitrescu, 2002).

Human Studies

In addition to Bowlby (1982), one of the major contributors to research on the effects of early caregiving deprivation on psychological development is Rene Spitz (e.g., 1965), whose work is notable for its use of observational methods, interest in individual differences in normal and abnormal development, emphasis on experience over fantasy, and interest in stepping away from psychoanalytic structure and dynamics in the infant that were out of line with what is known about cognitive development (Peterfreund, 1978).

Among children whom he described as showing anaclitic depression, Spitz (1965) noted that all children affected (19 of 123 studied in the nursery setting) experienced a prolonged (defined as 3 months) separation from mother between the 6th and 8th month of life. He further noted that, when mothers were able to return to the children, most of the children recovered. Nevertheless, he wrote, "It is doubtful if the recovery is complete; I would assume that the disturbance will leave scars which will show in later years; conclusive evidence of this is still lacking" (p. 272). Spitz provided further follow-up data on the children and, from these data, concluded that reunion with the mother was associated with a substantial gain in developmental quotient points that were lost during the separation period; infants who experienced a separation lasting longer than 5 months did not show recovery in the follow-up period. Progress and disturbance were perhaps most easily quantified in terms of developmental quotient, but disturbance and recovery in emotional and social behavior were parallel.

The early human studies on the effects of deprivation by Spitz, Bowlby, and others suffered from methodological shortcomings of several types and were justifiably criticized (A. M. Clarke & Clarke, 2000; Rutter, 1981). Yet, several of the methodological limitations of these earlier studies have proved difficult to resolve (e.g., for ethical reasons). Nevertheless, early clinical investigators were sensitive to many of these limitations. So, for example, Spitz (1965) noted that the child's relationship with the mother prior to separation was a strong determinant of the child's adjustment to the separation.

More recent data from human studies have provided a second major wave of findings on the effects of caregiving deprivation, as several groups in the United States, Canada, the United Kingdom, Greece, and elsewhere have tracked the development of children who experienced early institutional deprivation. These studies provide the sort of natural experiment to examine the effects of early caregiving deprivation on children's development because exposure to deprivation was relatively precisely timed and restricted to the early months or years of life, after which the children were adopted into low- to normal-risk families. Thus, these studies are positioned to examine whether the effects of early deprivation persist in the absence of ongoing and concurrent deprivation. None of these studies is immune from methodological shortcomings, which is to say that whatever their benefits, natural experiments cannot provide the methodological control found in planned experimental studies.

Research on the effects of caregiving deprivation on attachment and social behavior includes studies of institutional settings that vary widely in terms of the degree and severity of deprivation; however, lack of opportunities to form selective or discriminating attachment relationships is a major commonality, and likely a causal factor (Bowlby, 1951; Chisholm, 1998; Freud & Burlingham, 1973; O'Connor et al., 2000; Provence & Lipton, 1962; Roy, Rutter, & Pickles, 2004; Spitz, 1965; Tizard & Rees, 1975; Vorria et al., 2003; Wolkind, 1974). There is remarkable consistency among studies in describing a behavioral disturbance that is referred to in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, as the inhibited form of a Reactive Attachment Disorder. Children exhibiting this disturbance show a marked indiscriminate social approach to strangers, an apparent willingness to wander off, and a failure to check back with caregivers in situations that would be expected to curtail exploration, increase wariness, and increase proximity to a caregiver. Questions remain about basic features of the phenotype, but at least in early childhood, there is growing evidence that this disturbance can be differentiated from forms of insecure attachment found in children who had the opportunity to form selective or discriminating attachments to caregivers, however insensitive those caregivers were (O'Connor, Marvin, et al., 2003).

Findings from the English and Romanian Adoptee Study has provided some of the strongest evidence to date that early institutional deprivation is associated with persisting disturbances in attachment and social relations in the absence of ongoing deprivation. That study followed up a

sample of 165 children adopted into the United Kingdom after experiencing institutional deprivation that ranged from the first few months of life to 3½ years; these children were studied alongside 52 early-placed, within-U.K. adoptees who did not experience institutional deprivation. Children were extensively assessed at ages 4, 6, and 11 years (O'Connor et al., 2000; O'Connor, Marvin, et al., 2003; Rutter, O'Connor, & the English and Romanian Adoptee Study Team, 2004).

Several findings stand out from the longitudinal follow-up. First, at each assessment, the effect of duration of institutionalization was strongly associated with attachment disorder-related behavior in a dose-response manner. The absence of a threshold effect is an important observation insofar as it contrasts with the pattern from the animal data, including data for nonhuman primates. Second, early institutional deprivation predicted *persisting* deficits. For example, analyses of data collected at ages 4 and 6 years found considerable stability of individual differences ($r = .59, p < .001$) and no mean decrease in disturbances over time. This pattern of persisting problems is in contrast to other outcomes for which considerable improvement was observed in the same time period, notably quasi-autistic behavior (Rutter et al., 1999). Data on attachment relationships at age 11 years suggested a mixed picture of persistence and improvement (O'Connor, 2003). On the one hand, there was still a robust dose-response connection between duration of deprivation and disinhibited behavior at age 11 years. The magnitude of association between duration of deprivation and total score on the disinhibited attachment disorder behavior scale was nearly identical at ages 6 and 11 years ($r = .31$ and $r = .38$, respectively) for the 150 children on whom data were available. On the other hand, fewer children at age 11 years exhibited symptoms; for example, in those children adopted after 2 years of age, the rate of severe attachment disturbance decreased from 33% at age 6 years to 24% at age 11 years. Of particular importance, however, the overall decrease in symptoms was comparable across all children regardless of the age at entry into the United Kingdom. Thus, we can reject the possibility that the overall decrease in severe attachment disturbance in the Romanian sample was attributed to the children who were older at adoption (and who therefore had spent less time in a normal caregiving environment at the earlier assessment) "catching up" to the earlier placed children. Also, because the definition of attachment disorder symptoms was constructed for preschool-age children, it is possible that the disturbances seen at age 11 years did not carry the same meaning as at the earlier assessments (in

fact, basic research is still needed to define the phenotype of attachment disorder past preschool age). If that is the case, some of the decrease found may reflect a decreased age sensitivity in defining the disturbance.

A second key finding was that there was substantial individual variation in attachment outcomes. Whereas some children showed severe impairment according to multiple indicators of attachment disturbance, other children showed no such disturbances and were classified as exhibiting a secure attachment according to the modified separation-reunion procedures (O'Connor, Marvin, et al., 2003). A comparable degree of variation was even observed among the sample of later-placed children who experienced at least 2 years and up to 3½ years of institutional deprivation. Indeed, it is striking how much variation there was given the duration and severity of deprivation.

A third finding of note was that individual differences in attachment outcomes and the degree of persistence were not apparently related to characteristics in the adoptive home environment (e.g., parent-child interaction quality observed in the home). The persistence of effect in a minority of children, despite many years in a low- to normal-risk family environment, is incompatible with the life span or cumulative effects hypotheses: In the absence of concurrent adversity, the effects of institutionalization on child-parent attachment disturbances persisted in a sizable minority of children.

The biological bases of these disturbances in attachment and social relationships have not yet been identified, but several candidates exist. Oxytocin is an obvious candidate because it has been linked in animal studies with parenting, affiliation, pair bonding, and other forms of social relationships (Carter, 1998; Fleming & Corter, 1988; Francis, Young, Meaney, & Insel, 2002; Insel, 2003; Lovic, Gonzalez, & Fleming, 2001). Progress in this area in humans may be limited, however, because the meaning of peripheral oxytocin (i.e., outside the central nervous system) is unknown and may not be closely connected with oxytocin in the brain. A second line of research might pick up on the observation that a minority of children who experience deprivation do not seem to find social relationships especially rewarding or pleasurable. That is, not only are there clear deficits in social connections, but there is an additional difficulty of these children not seeming to want to engage with others. That, at least, is a finding from clinical and anecdotal reports. Interestingly, a similar observation is made of monkeys who experienced early deprivation (Cameron, 2004). A search for reward systems in the brain might yield insights into the motivational aspects of attachment and how they may be undermined by early deprivation

(Insel, 2003). Involvement of dopaminergic pathways might be relevant here and might explain not only disturbances in attachment behavior, but also disturbances in attention that are commonly reported in children with attachment disorder behavior (O'Connor et al., 2000). A separate line of investigation, using a genetic knock-out mice model, has shown that animals lacking the μ -opioid receptors show deficits in several types of attachment behavior (Moles, Kieffer, & D'Amato, 2004). The authors suggested that their observations may provide a basis for severe attachment disturbances found in children with Autism or Reactive Attachment Disorder. By showing that severe disruption in the opioid system can result in severe attachment and social behavior abnormalities, these findings offer a further focus for biologically based human research.

In addition to these neurochemical alterations induced by early experiences, imaging studies are beginning to piece together how deprivation might affect brain development. Chugani and colleagues (2001) found reduced glucose metabolism in children adopted into the United States from institutions in Romania compared with adult and child epileptic comparisons. Several brain regions were affected, including orbital frontal cortex, prefrontal cortex, and medial temporal structures that include the amygdala and hippocampus. The findings are of interest because they support previous animal work and are consistent with prior neuropsychological research on brain regions involved in social and cognitive deficits. Lesion studies in animals have also shown that damage to the hippocampal formation is associated with a range of behavioral disturbances, such as stereotypies and reductions in social interactions (Bachevalier, Alvarado, & Malkova, 1999). More imaging studies are needed to support these findings on the structural and functional consequences on the brain of early deprivation; this area will likely gain greater attention in the near future. The implication from these studies is that a multitude of biological mechanisms may be at play and may interact with one another in producing vulnerability.

Given the complex nature of the behavioral effects that have been reported in most studies, it is probably unrealistic to expect to find disturbance in a single brain region to account for these observations.

Additional Illustrations

The focus on prenatal maternal stress/anxiety and caregiving deprivation is not meant to imply that these are the only paradigms considered in research testing early effects hypotheses. Many other examples of environmental experience have been studied, and, indeed, not all have concluded

that early experience is in some way essential. For example, Klaus and Kennell's (1976) hypothesis of a sensitive period after birth during which the mother needs to bond with the child to ensure healthy normal development was ultimately rejected, notwithstanding the animal data that continue to show evidence for this effect.

Another example of environmental adversity that is being increasingly incorporated into research to assess the persisting effects of the early environment is maltreatment (Nemeroff, 2004). It is now established that child maltreatment is associated with a range of adverse biobehavioral outcomes via a number of mediating mechanisms (Cicchetti, 2004). Several studies have sought to examine if these adverse outcomes can be linked specifically to early maltreatment (e.g., Bolger & Patterson, 2001). In general, available data do not allow firm conclusions to be drawn about the effects of early maltreatment *per se* because of the continuity in adverse caregiving environments experienced by children who experience early maltreatment. On the other hand, data from cross-sectional, prospective, and follow-back studies all suggest that there is at least correlational evidence that early maltreatment is linked with a number of early-appearing psychological vulnerabilities, including perception, decoding and response to facial expression of emotion (Pollak & Kistler, 2002; Pollak, Klorman, Thatcher, & Cicchetti, 2001), neurohormonal changes (Cicchetti & Rogosch, 2001; Teicher et al., 2003), stress reactivity (Heim et al., 2000), structural changes in the brain (Teicher et al., 2003), and many behavioral disturbances (Kim & Cicchetti, 2004; Rogosch & Cicchetti, 2004; Toth, Cicchetti, Macfie, Maughan, & VanMeenen, 2000). These findings provide compelling evidence of the types of effects associated with maltreatment and identify plausible mechanisms that might mediate long-term links between early maltreatment and long-term outcomes. If there are lasting biobehavioral effects of maltreatment on health and disease, the high prevalence of maltreatment means that this particular risk carries very substantial implications for public health.

Summary

Available data from human studies of prenatal maternal stress and postnatal deprivation are consistent with some of the key findings from animal studies in many ways. Most important, there is now evidence for lasting effects of these two types of early experiences. However, whereas sensitive period and programming models can readily account for the animal data, these models are less able to account for the extant human data. That is seen in the case of the severe

attachment disturbances associated with institutional deprivation. Findings from these studies challenge the existing models of early experience, as none is able to handle the combination of wide individual differences, a dose-response pattern of association, and, in only a minority of cases, persisting disturbance in the absence of contemporaneous risk. Thus, simple versions of many models of early experience can be rejected. Developing alternative models to explain how and under what circumstances early experiences may have lasting effects may benefit from considering studies that make greater use of experimental designs, notably the prevention and intervention research reviewed in the next section.

IMPLICATIONS FOR PREVENTION AND INTERVENTION

This section examines how findings from prevention and intervention studies can contribute to the debate on the persisting effects of early experiences. Several themes are emphasized. First, although many prevention and intervention studies are predicated on the view that early experiences can have persisting effects, few are specifically designed to test this premise. A second theme is that prevention and intervention studies can provide particularly strong leverage in resolving questions of early experience because of the experimental control they afford. The third theme is that public and policy debates in this area are well under way, and there are examples of good but also bad clinical practice linked to notions of how early experiences shape psychological development.

Targets of Treatment and Expected Gains

Developmental frameworks for preventive interventions now in place (Coie et al., 1993; Conduct Problems Prevention Research Group, 1992, 2002; Hinshaw, 2002; Reiss & Price, 1996) emphasize child development and the developmental challenges facing the child. Almost without exception, existing frameworks adopt a life span perspective on how early experiences—whether it is adversity or treatment—shape long-term development. Within this perspective, the question of whether or not the individual returns to normal development following intervention is attributable to receiving an adequate and sufficiently targeted dose of intervention for the range of problems exhibited, and not because the intervention was provided “too late” in development. To the extent that timing is important, it is not because of assumptions of sensitive periods. Rather,

interventions applied earlier in development may be more effective because it is easier to bring back to a “normal” developmental trajectory an individual who has only recently strayed onto a deviant course. Later interventions can be just as effective as early ones, but need to be far more extensive than earlier interventions and, at the extreme, might involve inpatient care. In other words, age of the child predicts the intensity of the intervention rather than possible intervention effectiveness (Cowen & Durlak, 2000; Olds, 2002; C. T. Ramey & Ramey, 1998).

The notion that an intervention may be especially effective in preventing disturbance if it is delivered at a sensitive period has been rejected in some quarters; in others, it is held up as a distinct possibility. This debate has not advanced, however, because there remain questions about the meaning of timing, as implied earlier, and there are considerable practical difficulties of delivering “comparable” interventions to children of very different ages. In the area of parent-child relationship quality, for example, effective interventions exist for children of all ages, from infants to adolescents. However, the kinds of interventions developed for these different age groups take different forms and are typically based on different theoretical models. Whereas parent-child interventions for infants and toddlers tend to adopt an attachment theory focus, interventions for school-age and older children tend to adopt a social learning theory model. Thus, at present, it is difficult to see how timing could be injected into a study design, at least in the area of parent-child relationship and child adjustment, one of the most active areas of intervention research: Timing would be confounded with treatment type.

Intervention timing is thought to be important in a variety of other contexts, including those involving psychological mechanisms. In the area of cognitive-behavioral therapy for children, there is some evidence that older children respond more positively and that this may be accounted for by the greater sophistication to access cognitive processes that mediate treatment (Durlak, Fuhrman, & Lampman, 1991). Another example concerns intervention for substance use, for which there is a suggestion that programs are most effective if delivered prior to the initiation of or experimentation with substance use; interventions delivered after that period may be ineffective (Dishion, Kavanagh, Schneiger, Nelson, & Kaufman, 2002). Thus, in this case, timing may need to be defined in terms of stage of disturbance or exposure level or opportunities.

Research on mood disorders suggests that timing of the disorder may be important for intervention and recovery. For example, several studies show that first episodes of de-

pressive illness may be linked with psychosocial factors, but subsequent episodes are more autonomous from psychosocial risk, and that may be increasingly so with repeated episodes (Post, 1992). The implication is that the initial episode may make the individual more vulnerable to subsequent episodes because of neurobiological changes brought on by the illness (Post, Weiss, & Leverich, 1994; see also, Clarke & O’Callaghan, 2003). If that is so, the treatment implication is that the earlier treatment is administered, the less likely the individual will be neurobiologically sensitized and vulnerable to recurrent episodes. In this case, timing is not tied to development, but to the presumed progression of the disease and its effect on the brain.

As some of these examples illustrate, the suggestion that timing is important is not the same as suggesting that early intervention is essential. Adolescence is characterized by considerable biological changes, such as neuronal overproduction to alterations in neurotransmitter levels and genetic expression. This has led several researchers to question whether the periadolescent period might constitute an opportune time to intervene to reduce previously induced biological vulnerabilities. Evidence of success has been shown in a rat model, in which adolescent-onset treatment was effective for reducing the social behavioral effects of prenatal maternal stress (Morley-Fletcher, Rea, Maccari, & Laviola, 2003). At a minimum, these data suggest that the window of opportunity to alter biological mechanisms may extend beyond early developmental periods, or that windows of opportunity reopen (possibly involving different mechanisms from those involved at earlier developmental stages). What is not clear is if that window of opportunity is continuously open or, like brain development, shows marked discontinuity in development. Further research along these lines will likely yield important clinical insights and basic information on the malleability of central mechanisms involved in mediating the effects of early stress exposure.

Finally, there is growing evidence of a connection between the mechanism thought to account for persisting effects and the focus of (biologically based) treatments. Because HPA axis dysregulation is an established risk for and correlate of psychiatric disturbance, and because conventional pharmacological agents are also known to affect HPA axis functioning, it is currently a focus for treatment (Arborelius, Owens, Plotsky, & Nemeroff, 1999; Kaufman, Plotsky, Nemeroff, & Charney, 2000). If treatments of this sort prove effective, then the benefits can be measured in terms of greater clinical options and in terms of scientific evidence of the correctability of HPA axis dysregulation—

an issue about which there is little available information in humans. Treatment failures would also offer important lessons. Thus, resistance of the HPA axis to pharmacological intervention in adulthood might signal a degree of programmability that may match what has been found in the animal literature.

Model, Illustrative, and Sample Intervention Programs

As noted, very few examples of a timing effect on intervention are available. Nevertheless, examples do exist of early interventions having robust and lasting effects, with most focusing on some aspect of academic success/school readiness (Barnett, 1995; Campbell & Ramey, 1994; Reynolds, 1994; Reynolds & Robertson, 2003). One such example is the Abecedarian Project, a longitudinal study of the effectiveness of an intervention with high-risk children who were randomly assigned to treatment or control conditions (Campbell, Pungello, Johnson, Burchinal, & Ramey, 2002; Campbell & Ramey, 1994). Three treatment groups were compared with the control group. One group of children were given the intervention from infancy through 3 years of schooling; a second group received the preschool treatment only; a third group received only the school-based treatment. Each group consisted of approximately 25 children. Findings at age 12 years (Campbell & Ramey, 1994) indicated that the children who received the continuous intervention from infancy scored highest on intellectual and achievement tests; children who received only the preschool intervention performed lower, and lower still were children who received the intervention only from school-age. Each of these intervention groups performed better than the control children, but all groups performed worse than a nonrisk comparison sample. Interestingly, what was important for predicting age 12 outcomes was whether or not the child received the intervention in the preschool period. A further follow-up at age 21 years revealed that the early intervention continued to have long-term effects on cognitive and academic outcomes. However, the role of early experience in this study remains unproven because the children who received the early intervention received more years of intervention than those who received the intervention starting in school.

Reports of findings from the Chicago Child-Parent Center (CPC; Reynolds, Temple, Robertson, & Mann, 2001) program are important for additional reasons. The CPC provided comprehensive educational, family, and health services to children living in 25 sites in Chicago character-

ized by dense areas of poverty. Long-term follow-up analyses of the children in the study contrasted those in the index group of 989 children who received preschool and school-age services with a comparison group of 550 children who received alternative early intervention programs (these comparison children were entitled to services given their level of poverty, and so no child could be refused treatment). The CPC has advantages of an effectiveness rather than efficacy design, but also has some attendant methodological disadvantages, such as a comparison group that received uncertain treatment and variation in the amount and duration of treatment in the index group.

Analyses of outcomes at ages 18 to 20 indicate that children in the CPC preschool program had higher rates of high school completion by age 20 than comparison children (49.7% versus 38.5%) and a lower rate of school dropout than comparison children (46.7% versus 55%). Program effects were also detected in official arrest data; for example, 16.9% of children in the CPC program were arrested by age 18, compared with 25.1% in the comparison group. Program effects also carried over to need for remedial services; for example, 14.4% of the index children required special education placement, compared with 24.6% in the comparison group. These findings attest to significant and clinically meaningful differences and the persistence of effect into late adolescence/early adulthood despite the program's officially terminating in third grade.

One other feature of the study is that not all children received the intervention from preschool through school-age. Therefore, as with the Abecedarian Project, it is possible to contrast the outcomes of children who received early intervention only—in the CPC case, through preschool—with children who received more protracted intervention—in the CPC case, into third grade. It may not be possible to make any strong deductions from these comparisons because the opportunity to compare these subgroups of children arose serendipitously rather than through design. Nevertheless, the results are of interest. In particular, findings showed that school-age participation was not associated with a significant gain over the preschool intervention for the educational attainment or delinquency outcomes, but did confer additional benefit for the use of school remedial services. Specifically, participation in the school program (for at least 1 additional year) predicted modestly lower rates of special education, grade retention, and years of special education services compared with children whose receipt of the intervention stopped after preschool (Reynolds et al., 2001). That finding suggests that we might expect some but not other outcomes to show an effect in

direct proportion to the length of intervention, whereas other outcomes may show effects particular to early intervention *per se*. What cannot be easily predicted from existing data from the CPC or any other study is which outcomes might benefit from ongoing, cumulative impact and which outcomes seem more sensitive to early intervention effects.

Another model program of early intervention comes from the well-known work of Olds, Kitzman, and colleagues (Kitzman et al., 1997; Olds et al., 1997, 2004). Their nurse home visiting program, now replicated in diverse urban, rural, and minority samples, has shown that interventions starting in pregnancy have effects that may last into adulthood and affect a range of outcomes that were not initially targeted. That means that the cost-effectiveness is substantial (as well as complex to calculate) and that program effects probably come about via broad-ranging and interconnected psychosocial processes.

These studies may not have been designed to demonstrate that it is early experience *per se* that matters, but they do demonstrate the positive cumulative or even multiplicative effects of influencing the developmental trajectory at an early age.

An additional set of intervention studies deserving attention targets children who experienced extreme deprivation. Zeanah and colleagues (2002) reported that improving the child:staff ratio and increasing consistency of staff led to sizable decreases in severely disturbed or disordered attachment behavior associated with institutional rearing. This is one of the few instances of how an enriched environment, or, more accurately, a reduced deprivation environment, can lead to positive improvements in humans (A. D. B. Clarke, Clarke, & Reiman, 1958; S. L. Ramey & Sackett, 2000; see also, Duyme, Dumaret, & Tomkiewicz, 1999). Given the unfortunate and inevitable commonplace nature of institutions to care for children because of war and parental death by AIDS and other factors, further research of this type is needed to show how institutional care may be organized to reduce the likelihood of those disturbances most closely linked with institutional rearing.

Studies that follow children who were adopted following institutional rearing provide an important and complex footnote to the findings on intervention. Although none of these studies was designed as an experimental intervention, each examines the effect of probably the most extreme type of intervention: adoption. For some outcomes, notably physical development, catch-up may be swift, dramatic, and, in many cases, essentially complete. However, these same longitudinal follow-up studies also show limited evidence for complete catch-up in other areas, most notably social outcomes. In the specific case of attachment, for ex-

ample (O'Connor et al., 2000), the amount of improvement observed in children following adoption was modest or even undetectable between 4 and 6 years, and what positive change that was observed could not be explained by the later-placed children catching up to their earlier-placed peers' level of functioning.

Not all early interventions are effective, or may be effective only for subsamples of those individuals treated. For example, the 8-year follow-up of a large sample of children who received an early intervention to compensate for low birthweight found no lasting overall effects. Intervention effects were detected, but only in the heavier low birthweight premature children (McCarton et al., 1997). That may well have been expected and may have a compelling biosocial explanation. Findings from the Infant Health and Development Project noted earlier illustrate that intervention studies may need to target vulnerable individuals, even in already carefully targeted samples. In other words, as our models of biopsychosocial risk become more sophisticated, so, too, must our expectations of for whom interventions would be most effective.

Finally, it is worth noting that there are many naturally occurring examples of interventions that can test timing effects. The most common is age at starting school and, more broadly, the recognition that schooling *per se* (i.e., without any form of additional enrichment) is a type of intervention that has beneficial effects (Gorman & Pollitt, 1996).

Results from many projects, including the ones already reviewed, demonstrate that early intervention projects can alter life course trajectories and that the gains in important public health outcomes may more than offset costs of service delivery. On the other hand, many of these same studies show that the outcomes of the treated group are still poor relative to those in the nonrisk comparison group, indicating that even the most effective preventive interventions delivered early in development may not eliminate the effects of the preexisting risk.

Public and Policy Debating Points

Several books (e.g., Bruer, 1999) have taken on the question of whether the 1st months or years of life represent a critical or sensitive period in human development, with the corollary that it is essential that interventions are delivered during this period if the effects of early adversity are to be eliminated and optimal development is to be achieved. A key thesis of Bruer's book is that the case for early intervention has not yet been proven, and that the neuroscientific evidence collated to support such claims is preliminary or, in some cases, overextended. That view has

generated controversy but is consistent with the available evidence. His thesis was premised on the fact that there are comparatively few interventions that are designed to test the early (versus later) experience hypothesis. This is not to say that we do not have evidence that early interventions are not effective or do not have lasting effect. As described above, there are many such demonstrations. Instead, the point is that most of the interventions showing substantial clinical effect cannot rule out the hypothesis that similar interventions delivered later in development would not have comparable effects. That is an issue that may not be at the forefront of social policy (offered an option of a proven intervention, most clinicians and policymakers would be happy to advocate for it, whether or not it supports a particular early experience hypothesis), but it is an important scientific issue that has gone under-researched.

Whatever the state of the debate of the role of early experiences, there is general recognition that, ultimately, understanding the effects of early experience on later development is not a purely scientific matter, but one with public health implications (e.g., Dawson, Ashman, & Carver, 2000). There are, in fact, many examples in clinical practice that are based on judgments about the effects of early experience and the mechanisms by which early adversity has persisting effect, including bad practice. It is worth describing one example to illustrate that there are important costs associated with wrong theory and distorted notions of early experience.

As discussed earlier, there is considerable evidence in humans that early caregiving deprivation is associated with severe and persisting disturbances in attachment and social relations in a minority of children. Parents' concerns about these children, many of whom were adopted from overseas institutions, were often met with uncertain and inadequate responses from child mental health professionals. Many parents then turned to alternative treatments that were aggressively promoted for children with a real or suspected Reactive Attachment Disorder. The treatment promoted for these children in select circles is broadly referred to as holding therapy. This treatment approach is based on "rage reduction" techniques, which presumed that the disordered child put up defenses against the outside world because of past experiences of trauma. There was the further proposal that radical forms of intervention were necessary to "break through" the child's defenses to access the child's hurt/trauma. Once accessed, that early trauma could then be resolved and normal development would proceed. These interventions also borrowed and distorted features of attachment theory to justify the holding treatments. So, for

example, it was proposed that the child's lack of sensitive care and touch in infancy could be redressed by intensive holding in childhood; some practitioners even coerced holding to stimulate the regression to infancy that was thought to be necessary for successful treatment. Underlying this treatment were proposals that the effect of early caregiving deprivation could be permanent, had a presumed (but not confirmed) neuroscientific foundation, and required radical intensive intervention to resume normal development.

It is hardly surprising that there is no evidence that these methods are effective in treating attachment problems; that could have been predicted from their mistaken conceptual foundation. Nevertheless, these treatments continue to be aggressively promoted on the Internet and elsewhere. This is despite the fact that several professional organizations have made statements exposing the coercive form of holding therapy as dangerous and the existence of legislation specifically prohibiting coercive forms of holding therapy in several states. The case of holding therapy for attachment disorder is perhaps the most striking example of how misapplication and misunderstanding of theory and research on early experience have had dangerous consequences for children and their families.

One likely reason this form of inadequate and dangerous treatment has persisted is the slow and muted style in which evidence-based clinical investigators have engaged in the debate on this treatment. Fortunately, that is now changing, but evidence-based practitioners have an uphill battle to inform the public and correct widely dispersed mistaken notions concerning early experience and psychological development.

Summary

A thesis of this chapter is that intervention studies will likely play an important role in differentiating alternative hypotheses concerning the role of early experience on long-term adjustment. This view derives, in large part, from the difficulty of naturalistic studies to disentangle early effects from cumulative or concurrent experiences. However, such studies are rare, and what little data do exist are insufficient to test alternative predictions concerning the mechanisms by which early experiences confer risk for long-term adaptation. To date, the role of timing of the intervention as a predictor of program success is less certain because there are very few interventions comparing the effectiveness of interventions delivered early versus later in development.

CONCLUSIONS AND FUTURE DIRECTIONS

This concluding section focuses on some of the promising future directions for research on early experiences. This discussion is organized by three overarching themes: the notion and strategy of translational research, individual differences, and the use of research designs and paradigms.

Translational Research

The concept of translational research is now firmly rooted as a mission or a strategy for research. It is a concept that needs some unpacking. Several kinds of translations are implied by the term, including preclinical to clinical research and the move from basic biological processes to behavioral phenotypes that attract clinical attention. Regardless of which sort of translation is implied, however, the underlying general notion is that there is substantial basic knowledge that, for one reason or another, has not yet filtered into practice, whether the level of practice is the individual clinician or a community-level initiative.

Future research on the role of early experiences needs to heed this call to translational research. That can be interpreted and accomplished in a number of ways. One is by focusing on the concept of timing in development. Basic research findings from animal experiments have made a strong case for timing, based on a growing database of ontogenetic periods and processes. On the other hand, this information has not been widely incorporated into human research using observational or intervention designs. That may reflect the only recent shift in considering the hypothesis that there may be persisting effects of early experience or genuine difficulties in mapping the boundaries of potentially sensitive or vulnerable periods in human development. Nevertheless, research of this sort may yield valuable basic and applied information. Intervention studies are now moving to a point of asking for whom interventions are effective. A somewhat parallel question can be added to that list: Intervention studies are now justified in asking when in development the intervention is likely to have the strongest effect.

A second form of translation needing additional attention is that linking brain, biology, and behavior. One of the potentially more promising avenues for this sort of integrative research is to incorporate biological mechanisms within experimental intervention designs. The benefits of such a study are clear enough: We need to understand not only that the intervention effects a behavioral change, but also what the underlying and sustaining mechanisms are.

The early intervention/prevention studies may be especially well suited to this sort of translational research. To date, many of these studies do not include measures of brain development, but they do point to a pattern of behavioral development and change whose biological basis may be very amenable to current assessment techniques (Bachevalier et al., 1999; Goldman-Rakic, Isseroff, Schwartz, & Bugbee, 1983). The conceptual case for multivariate, multilevel, biopsychosocial models of applied research is compelling. Promoting further progress in this area is not merely a matter of a conceptual imperative, however, but will require additional training and, likely, creative funding mechanisms.

Individual Differences

One of the most striking observations from human research that has followed children who experienced severe early adversity is the wide array of individual differences in long-term adjustment. There are numerous examples for each of many major serious risk factors. Findings of children who experienced early institutional deprivation are perhaps most telling about the importance of individual differences. These children have experienced arguably the most severe form of adversity—far in excess of high-risk samples in most studies—and for a prolonged period of time. In the course of their deprivation experience, the children completely missed out on sensitive parenting and attachment experiences, affect attunement, opportunities for emotion regulation, cognitive stimulation such as scaffolding, and many other psychological processes that have been linked with healthy development in diverse samples of children. Yet, although there are clear difficulties in the long-term social and cognitive development of *some* children, many children have shown remarkable resilience and appear to be functioning well within normal limits; other children are thriving. Given that at least some of these studies used systematic ascertainment and stratified sampling strategies, we can rule out the possibility that there is a major selection bias in those who participate in this sort of research (in any event, the degree of individual differences is substantial regardless of how the sample was obtained). Arguably, then, one of the most important lessons from contemporary studies of children adopted from institutions is that individual differences are retained under even the most severe forms of environmental deprivation. It is interesting that there is not such an obviously wide degree of individual differences and outcome diversity in the animal research.

What are the implications of the strength of individual differences for future research? Two are suggested. One is that research hypotheses need to be tailored more to individual differences and the certainty of outcome diversity, whether the exposure is adversity or, just as important, intervention. Predicting an overall group change is obviously important in showing that an intervention may have import value in serving a wide and diverse community. Alternatively, variation within the group that received the intervention is likely to be as large and as important as the variation between the treated and nontreated groups. Accounting for this within-group variation is important both for refining the interventions and for informing developmental theory.

The second implication is that individual differences are a natural conceptual framework for incorporating and integrating research on genetics, early life experiences, and life course experiences in predicting well-being. Inevitably, however, there are statistical power considerations that will limit how broad the research models can be, and that may prove especially problematic for specific risks (be they genetic or environmental) that are expected to have important but small effect sizes.

Research Paradigms

The third area of future study concerns the paradigms used in animal and human research, particularly their compatibility and ecological validity. The basic underlying question here is one of generalizability: Can findings from one type of study of early adversity project general lessons for early experience, or are the implications likely to be limited in scope and the type of outcome assessed? This has emerged as an important recent issue in the animal research, as several studies have begun to document that specific stresses (auditory versus shock, for instance) may have differential effects. That may not be wholly surprising, but it does raise questions about how specific the fit is between risk exposure and outcome.

The degree of generalizability of findings across diverse risk exposures in humans also requires additional research attention. The study of children adopted from institutions again provides a useful illustration. Studies of formerly institutionalized children show perhaps better than any other study that there is tremendous resilience in human development and that the limits of this resilience are limited. Once we move beyond that broad fact to consider more specific outcomes and mechanisms, however, the issue of generalizability emerges. On the one hand, the kinds of behavioral

and emotional disturbances found in formerly institutionalized children differ from those in “ordinary” high-risk settings, notably the sort of Reactive Attachment Disorder-like behaviors. Even where similar problems emerge (e.g., inattention/hyperactivity), they may take on a slightly different form and/or have different sets of co-occurring problems from what is typically found. Collectively, these findings suggest that the differences between formerly institutionalized and ordinary high-risk samples may be different not only in degree, but also in kind. Does the latter finding imply different brain regions? Perhaps not, but these findings do underscore the need for a firmer biological basis of how early adverse experiences get translated in brain processes, and how these processes are then carried forward to continue to shape development.

In addition to strengthening the biological background to research paradigms, a key implication is that future efforts to assess the role of early experiences need to emphasize comparative approaches, comparing across species and across research paradigms within species.

Given the central significance of understanding the effects of early experience on the development of psychopathology, it is surprising that comparatively few studies are designed to assess this issue directly. The difficulty in addressing this issue is not simply a matter of conducting long-term longitudinal studies, but rather in providing the kind of data that would differentiate alternative models of early experience that now guide animal and human studies.

Extant human databases from naturalistic and intervention studies may be adequate for guiding major clinical and policy decisions, but they are inadequate for resolving core debates concerning the long-term effects of early experiences and the mechanisms that underlie these effects. This important limitation of existing research has kindled controversy and will continue to spur further creative and rigorous research efforts.

Fields, like children, develop at uneven rates. For any individual child, some time periods feature only slow and steady development, whereas other periods show rapid, almost overwhelming, advances. Such rapid advances best characterize the past 10 to 15 years of research in mental retardation. During this period, totally new topics appeared and researchers endeavored to tie historically prominent areas to new issues and concerns. Overall, the period from about 1990 can be characterized as a time of renewed interest, excitement, and rapid scientific advance.

One way to appreciate these advances is to compare the current chapter to the mental retardation chapter in *Developmental Psychopathology's* first edition, published in 1995. In that first chapter, Hodapp and Zigler (1995) described the history of developmentally oriented work in mental retardation; the two-group approach; similar sequences, structures, rates, and transitions; and personality-motivational variables, mother-child interaction, and families. Although we revisit several of these topics in this chapter, virtually every topic features new findings that

changed the way we had previously thought. Indeed, the amount of new work in each area is staggering.

But even more remarkable is what was not included in that earlier chapter: issues that were either never or only slightly discussed in the early to mid-1990s. These many topics pertain to research groups in mental retardation research, the age groups studied, and the family and other contexts in which these individuals develop. In terms of populations, the 1995 chapter included only short discussions of the effects of genetic etiology on children's development because the many findings concerning Down syndrome, Prader-Willi syndrome, Williams syndrome, and other genetic disorders were still mostly on the horizon. Even more fundamentally, how one should consider different research groups, how one should compare or contrast such groups, how behavioral profiles change with age (and why) were all unknown and, for the most part, not yet even actively discussed. Similarly unknown were ties of behavioral profiles to specific brain structures, development, and functioning.

Beyond development of children themselves, a decade ago we as a field were also much less clear about a host of issues relating to the contexts of development. For example, researchers have only recently examined how behaviors commonly seen in a particular genetic disorder might indirectly affect parents, siblings, teachers, friends, and others in the child's surrounding environment. So, too, has the entire issue of life span developmental approaches become prominent in developmentally oriented mental retardation studies during the past few years (e.g., Heller, 2004). Such work, though it has a long way to go, now encompasses both the life span development of persons with mental retardation themselves and of their families, a notion almost totally unexplored a decade or two ago.

Finally, we must appreciate that all of these advances have occurred against a background of both scientific and societal changes. Scientifically, advances in genetics have allowed for the discovery and specification of many genetic disorders. To give a few examples, Ewart et al. (1993) discovered in the early 1990s that a microdeletion on chromosome 7 was the cause of Williams syndrome; and in 2004, M. G. Butler, Bittel, Kibiryeva, Talebizadeh, and Thompson found that there are two behaviorally distinct deletion forms of Prader-Willi syndrome. In the same way, the technological advances behind structural and functional brain imaging have only recently come online, allowing for the specification of brain areas responsible for particular high-level behaviors.

Changes in society also constitute an important backdrop. Consider the entire topic of life span development. Until the past few decades, individuals with such genetic disorders as Prader-Willi syndrome or Down syndrome did not live into middle age or old age. Today they do. It has become imperative to determine how these individuals function throughout the adult years, and how certain disorders (e.g., Down syndrome) relate to other aging-related diseases (Alzheimer's). Moreover, such changes will intensify in the future. At present, 526,000 individuals 60 years and older with disabilities live in the United States; that number is expected to triple—to 1.5 million—by the year 2030 (National Center for Family Support, 2000). Advances in developmental approaches to mental retardation cannot be considered apart from changes in other scientific areas and in society at large.

In the early years of the twenty-first century, then, examining developmental approaches to mental retardation involves more than updating per se. We seem on the cusp of a new, even revolutionary, era, a time in which a developmental psychopathological view toward mental retardation seems more important and timely than ever.

To provide a flavor of the newest perspectives and advances in this area, we begin with a short description of the role of mental retardation from the perspective of developmental psychopathology before providing a brief summary of historical forays into this area. We then devote a section to the population itself, beginning with Zigler's (1967, 1969) two-group approach and then describing children with various genetic etiologies. Throughout these discussions, we also tackle the question of behavioral phenotypes and briefly hint at several methodological issues. We update several aspects of organismic development, particularly sequences and cross-domain relations. We then provide more extensive discussions of families, parents, siblings, and other contextual issues before concluding this chapter with a section discussing directions for the decades to come.

TIES OF MENTAL RETARDATION TO DEVELOPMENTAL PSYCHOPATHOLOGY

In the field of developmental psychopathology, mental retardation is unique. On one hand, mental retardation is essentially defined by a single developmental criterion: a significant delay in general cognitive development (along with adaptive impairments that generally accompany such cognitive deficits). Paradoxically, 1,000 different disorders can cause mental retardation.

To some extent, mental retardation is not a tangible disorder, like Autism or Obsessive-Compulsive Disorder, but a designation based on the construct of intelligence. Although failure at school, in the home, or in everyday life generally brings a child to the attention of professionals (MacMillan, Gresham, Siperstein, & Bocian, 1996), the formal diagnosis of mental retardation is made using performance on behavioral tasks to infer underlying levels of reasoning processes. In addition, deficits in intelligence, at least during the childhood years, are defined by discrepancies between the child's rate of intellectual development compared to typical, nonretarded children. Indeed, prior to the mid-1970s, IQ was defined in terms of developmental rates, as indicated by the historical formula "MA (mental age) divided by CA (chronological age) multiplied by 100."

Two other issues pertaining to mental retardation are noteworthy. First, the pattern of IQ subtest scores is irrelevant to the mental retardation diagnosis. As long as the final score falls below the IQ cutoff, the child or adult is considered to have mental retardation. Despite advances in understanding the genetic contributions to intellectual development (Iarocci, in press; Spinath, Harlaar, Ronald, &

Plomin, 2004), mental retardation reflects an arbitrarily chosen cutoff score of a gross behavioral measure of intellectual processes.

Second, the precise IQ cutoff has changed over time. Although an IQ of 70 or below has usually constituted the IQ cutoff, such has not always been the case. In Heber's (1961) manual of the American Association on Mental Deficiency (now American Association on Mental Retardation, the field's main professional group), an IQ cutoff of 85 and below was proposed. Later, Grossman (1973) moved the cutoff to IQ 70 or below. In 1992, the American Association on Mental Retardation (AAMR; 1992) proposed a cutoff of IQ 70 or 75 and below, before the IQ 70 and below cutoff was reestablished in the AAMR's 2002 manual.

Ironically, this single, arbitrarily designated measure of cognitive delay can arise from more than 1,000 different etiologies. These etiologies represent a smorgasbord of genetic, chromosomal, viral, and other physiological disorders. In addition, the developmental differences among these various disorders extend well beyond the degree of delay to unique cognitive-developmental characteristics that are sometimes so pervasive that they are clearly identifiable even when considering individual differences within a group (Burack, 1990; Burack, Hodapp, & Zigler, 1988, 1990; Dykens, Hodapp, & Finucane, 2000). Rates and trajectories of development, as well as profiles of relative strengths and weaknesses, are all highlighted in the more precise differentiation of various etiological groups.

Etiological differences also allow for unique insights into general developmental theory (for earlier reviews, see Cicchetti & Pogge-Hesse, 1982; Hodapp & Burack, 1990). To borrow a phrase from Urie Bronfenbrenner (1979), by studying different etiological groups, we begin to examine "experiments of nature." Such experiments of nature allow us to identify aspects of development that are universal, that occur in spite of vast differences across etiological groups, as opposed to aspects that might differ in different groups. Investigations of such issues are enhanced by researchers' ability to uniquely observe development in slow motion, thereby observing specific aspects of development that might not be observable when development progresses at a typical rate (Wagner, Ganiban, & Cicchetti, 1990).

Finally, behavioral differences across different etiological groups also relate to the very meaning of the term "development." In addition to sequences, stages, and other within-the-child developments, the reactions and behaviors of others to the developing child are part of developmental analyses. Just as the wider field of developmental psychology now includes more contextual and outside-of-the-child ideas within developmental frameworks, so, too, can con-

textual factors be included in developmental approaches applied to different etiologies.

We now turn to a brief historical background, highlighting questions of both what development is and how one should classify children with mental retardation.

HISTORICAL BACKGROUND

In addition to paying respect to the developmental forerunners of today's mental retardation field, this brief historical survey highlights the long-running tensions surrounding the contents of developmental approaches, the nature of the population to which these approaches are or should be applied, and the interplay between the two. As we hope to demonstrate, some of developmental psychology's most distinguished early theorists sensed these tensions and provided the groundwork for today's more detailed, more sophisticated analyses.

Heinz Werner

The first major early developmentalist to consider children with mental retardation is Heinz Werner. Although today Werner has been forgotten by many, he is historically best known for his grand theory of development. This theory is embodied in his orthogenetic principle, the view that development "proceeds from a state of relative globality and lack of differentiation to a state of differentiation, articulation, and hierarchic integration" (Werner, 1957, p. 126). This overarching theoretical principle was to be applied to such seemingly different phenomena as children, dream states, psychopathology, primitive societies, and "microgenesis" (or development "in the moment"), all issues studied by Werner and his students at Clark University.

Before his more well-known Clark University days, however, Werner worked from 1937 to 1943 as a research psychologist at the MacGregor Laboratories of the Wayne County Training School outside of Detroit. There, along with his colleague Alfred Strauss, Werner published approximately 30 studies on children with mental retardation (Witkin, 1964).

Several themes characterize this work. First, Werner (1937) originated the distinction between "process and achievement," the idea that the child's underlying mental processes were not necessarily equivalent to the child's achievement, or behavior. This realization amply demonstrated itself in children with mental retardation. In one study, children were asked to put together a multipiece

puzzle. Werner and Strauss (1939, p. 39) noted that, in contrast to nonretarded children, the children with mental retardation “merely put the parts together quite mechanically, taking care only that the edges of the different pieces agreed perfectly with one another.” By adopting this strategy, children with mental retardation could sometimes perform selected behaviors as well as their nonretarded peers.

Yet, in terms of the processes themselves, Werner (1957) generally viewed children with mental retardation as less developed, showing less “differentiation and hierarchic integration” than same-aged nonretarded children. In conceptualizing these children as developing normally but at slower rates than nonretarded children, Werner was the first major Western developmental theorist to apply theories of normal, nonretarded development to children with mental retardation.

Werner’s contributions also included the distinction between organic and familial mental retardation. Specifically, Werner (1941) felt that only those children showing no specific cause of their retardation—those who were “endogenous” in their mental retardation—necessarily showed “normal” (albeit slower) developments. Other children were not considered to follow the usual developmental progressions, specifically those whose mental retardation was due to such external or “exogenous” causes as Down syndrome, anoxia at birth, or other organic etiologies.

Jean Piaget and Barbel Inhelder

Although Heinz Werner may have initiated the idea of a general developmental approach, Jean Piaget allowed for the approach’s elaboration. Beginning in the 1920s, Piaget proposed a series of hierarchically organized stages with numerous specific, detailed sequences by which development occurred. Developmentally oriented researchers could then determine whether these sequences also held for children with mental retardation. In subsequent studies, Piagetian sequences were examined in children with mental retardation during the 1930s (Lane & Kinder, 1939), 1940s (Prothro, 1943), and 1950s (Woodward, 1959, 1963).

Most important, though, was the work of Piaget’s colleague Barbel Inhelder. In her studies of children with mental retardation of various etiologies, Inhelder (1943/1968) noted both similarities and differences between these children and children without mental retardation. Like nonretarded children, children with mental retardation also appeared to develop along similar sequences in various Piagetian domains. Yet, in other ways, children with mental retardation differed markedly from

those without. Inhelder pointed to regressions, incomplete developments, and oscillations in children’s responses between higher- and lower-level answers. She thus highlighted that children with mental retardation show more fits and starts, more tentative, more fragile development than do nonretarded children.

Lev Vygotsky

If Werner began and Piaget-Inhelder made specific the developmental analyses of children with mental retardation, Lev Vygotsky previews analyses that have yet to be done. Like Werner, Vygotsky worked with children with disabilities early in his career, from about 1924 to 1930 (van der Veer & Valsiner, 1991). His disability work centered on three major ideas: developmental analyses, mediation, and sociogenesis (Wertsch, 1985).

Like Werner and Piaget, Vygotsky was a “big picture” developmentalist who focused on many aspects of development. He was therefore acutely interested in how development occurs in children with disabilities. His focus was on how the child’s entire personality structure is reorganized in relation to a particular disability (Reiber & Carton, 1993). Vygotsky’s writings presaged ideas of compensation that permeate the wider field of developmental psychopathology.

A centerpiece of such developmental analyses involves mediation. Vygotsky conceptualized mediation in two ways: the adult mediating the child’s development and the child mediating his or her own development. In the first, more social sense, mediation involves mother-child interactions and other individual or societal contacts that aid the developing child. Concerning children with disabilities, Vygotsky was particularly interested in how special education should be performed and whether these children should be in contact primarily with others like themselves or with the wider society. His goal, always, was for children with disabilities to become fully functioning, fully contributing members of their society. In contrast to Werner and Piaget, then, Vygotsky’s mediational views contributed to current debates concerning integration, normalization, and how best to educate children with disabilities (Hodapp, 1998).

The third major theme in Vygotsky’s work involved sociogenesis, or the idea that higher developments occur as a result of interactions with adults. Such views led to Vygotsky’s (1978) zone of proximal development, probably his best-known idea among most Western psychologists. Even early on, Vygotsky applied this zone to children with men-

tal retardation (van der Veer & Valsiner, 1991). His idea was to use the width of the zone—the time between the child's successful behaviors with and without adult help—to predict future development in individual children with mental retardation. To Vygotsky, two children with mental retardation can have identical levels of current functioning (i.e., mental ages) but very different prognoses. If, with adult help, one child is able to perform higher-level behaviors than the other, that first child has a wider zone and therefore a better prognosis.

Overview

In considering the work of Werner, Piaget, and Vygotsky, several issues deserve mention. First, in comparing Vygotsky to Werner and Piaget, one sees an early instance of the debate about the meaning of the term development. Is development related to children alone, or do developmental analyses also include the child's larger environment or child-environment interactions? For the most part, Werner and Piaget focused on the child as their object of development (although Werner, 1926/1948, did address the "Umwelt," or larger environment of different organisms). Through Vygotsky's emphasis on sociogenesis, his interest in child-environment interactions, and his desire to understand how children thrived in society in spite of their disabilities, he would be considered the more context-oriented developmentalist.

A second issue pertains to the use of children with mental retardation as natural experiments (for a recent discussion, see Cicchetti, 2003). Just as researchers today examine children with mental retardation to determine the connections and disconnections among levels of various domains, so did Werner, Piaget, and Vygotsky examine mental retardation with an eye toward applying and testing their theories. Hence Piaget's (1943/1968, p. 10) exclamation, "We must admit that we did not suspect that this [Piagetian] method would become central in her [Inhelder's] everyday practice."

Third, the three developmentalists differ as to whether the cause of mental retardation is relevant to developmental analyses. Neither Vygotsky nor Piaget-Inhelder mention the child's etiology in their writings on the development of children with mental retardation. In contrast, Werner (1941, p. 253) distinguished between endogenous and exogenous mental retardation, noting that "the assumption seems justified that deficiencies of this sort [i.e., exogenous, organic causes] must impede the learning processes in a way peculiar to the type of mental deficiency." Al-

though he never became more explicit, Werner presaged Zigler's two-group approach to mental retardation, which in more recent years has evolved into studies examining developmental differences in children with different genetic (and nongenetic) causes for their mental retardation.

DEVELOPMENT IN CHILDREN WITH MENTAL RETARDATION: DOES ETIOLOGY MATTER?

The question of who constitutes the subject group has long pervaded behavioral research in mental retardation. This issue continues to this day, has important developmental repercussions, and constitutes an area of enormous progress over the past 10 to 15 years.

Historically within the field of mental retardation behavioral research, most researchers have had little interest in how children come to have mental retardation. Mental retardation per se was thought to be *prima facie* evidence of some type of "brain impairment," and little else mattered. Over the decades, then, one notes numerous statements, often from the major researchers on behavior in individuals with mental retardation, that etiology does not matter (see Burack, Evans, Klaiman, & Iarocci, 2001). In contrast is attention to Zigler's two groups of persons with mental retardation and then, later, to different specific etiological groups.

Zigler's Two-Group Approach

In contrast to those who argued that the cause or etiology of the child's mental retardation is irrelevant, Zigler (1967, 1969) proposed his two-group approach to mental retardation: one group that does not show clear organic cause and another that does.

Specifically, proponents of the two-group approach hold that the first group consists of persons who show no identifiable cause for their mental retardation. Such individuals are generally more mildly impaired and tend to blend in with other, nonretarded persons. Probable causes range from polygenic inheritance to environmental deprivation (or overstimulation); different persons may have different polygenic or environmental causes, or there may be an interplay between the two. In Zigler's (1967, 1969) original formulations, he conceptualized this group as constituting the lower tail of the normal or Gaussian distribution of intelligence. This type of mental retardation has been referred to as familial, cultural familial, or sociocultural familial; nonorganic, nonspecific, or undifferentiated; and

mental retardation due to environmental deprivation. This list highlights the discrepant beliefs about the causes of mental retardation in these individuals.

In contrast to those with cultural-familial mental retardation, other individuals show one or more organic causes for their mental retardation. Such causes include hundreds of separate organic insults. These insults can occur prenatally, perinatally, or postnatally. Prenatal causes include all of the 1,000+ genetic mental retardation disorders, Fetal Alcohol Syndrome (FAS), Fetal Alcohol Exposure (FAE), rubella, as well as all accidents in utero. Perinatal causes include prematurity, anoxia at birth, and other birth-related complications. Postnatal causes range from sickness (e.g., meningitis) to head trauma. In addition, those with organic mental retardation are more likely to show greater degrees of intellectual impairments; in most surveys, as IQ levels decrease, increasingly higher percentages of persons show an identifiable organic cause (Stromme & Hagberg, 2000).

Although various researchers (including Werner) had noted the existence of two groups of persons with mental retardation, Zigler was the first to make clear behavioral distinctions. In terms of behavioral development, children with cultural-familial—but not necessarily with organic—mental retardation were predicted to show both sequences and structures similar to those shown by typically developing children. Thus, the so-called similar-sequence hypothesis predicted that children with (cultural-familial) mental retardation should, like typically developing children, proceed in order through Piagetian or other normative stages of development. For the most part, this similar-sequence hypothesis has held true, even with children with various organic forms of mental retardation (e.g., Weisz & Zigler, 1979).

The second prediction, the similar-structure hypothesis, concerned the structure of cognitive-linguistic abilities from one domain to another. Specifically, Zigler held that cultural-familial mental retardation was not caused by any defect or deficit related to a single area of functioning. Instead, children with cultural-familial mental retardation were predicted to show a more generalized delay, affecting all areas of development to similar degrees, as evidenced by even or flat developmental profiles at the child's mental-age level. Much contradictory evidence exists concerning the similar-structure hypothesis, some even for children with cultural-familial mental retardation (e.g., Mundy & Kasari, 1990; Weiss, Weisz, & Bromfield, 1986; Weisz, 1990).

What about children with organic mental retardation? Here Zigler hedged his bets, believing that children with organic mental retardation might not follow universal se-

quences (similar-sequence hypothesis) or show flat or even developmental profiles (similar-structure hypothesis). To quote Zigler (1969):

If the etiology of the phenotypic intelligence (as measured by an IQ) of two groups differs, *it is far from logical* to assert that the course of development is the same, or that even similar contents in their behaviors are mediated by exactly the same cognitive processes. (p. 533; italics added)

Viewed from the early twenty-first century, one could criticize several aspects of this two-group approach. First, the approach lumps into a single organic group individuals with many different types of mental retardation. In Zigler's defense, his *Science* article appeared in 1967, just 8 years after Lejeune, Gautier, and Turpin (1959) discovered that Down syndrome was caused in most cases by a third chromosome 21. Genetic knowledge and technology were relatively undeveloped, and the identification of most genetic disorders was decades away.

By the late 1980s, however, Zigler and his colleagues were beginning to question the utility of classifying so many separate etiologies into a single organic group. Noting different IQ trajectories in children with Down syndrome, cerebral palsy, and boys with Fragile X syndrome, Burack, Hodapp, and Zigler (1988, 1990) suggested differentiating the organic category. Not only was the organic group composed of children with many separate etiologies, but these etiologies might also lead to different, etiology-related behaviors.

Genetic Etiology and Behavioral Phenotypes

Among the most important recent advances is the focus on behavior in specific etiologies of mental retardation. By examining individuals with over 1,000 different genetic mental retardation syndromes, one can see diverse strengths-weaknesses and connections-disconnections across domains of development. One can also begin to tie together genetic anomalies, brain functioning, and behavior, the gene-brain-behavior relationships that have been the focus of research on many different conditions. Beyond the individuals themselves, one sees examples of different reactions by mothers, fathers, siblings, teachers, and others in the child's environment. Finally, by separately examining functioning in different genetic disorders, one can envision more targeted behavioral, educational, pharmacological, and other interventions.

Figure 6.1 Behavioral research articles, 1980s versus 1990s.
Source: From “Genetic and Behavioural Aspects: Application to Maladaptive Behaviour and Cognition” (pp. 13–48), by R. M. Hodapp and E. M. Dykens, in *Intellectual Disabilities: Genetics, Behavioural, and Inclusion*, J. A. Rondal, R. M. Hodapp, S. Soreci, E. M. Dykens, & L. Nota (Eds.), 2004, London: Whurr.

But before describing these many advances, it is instructive to document the move toward etiology-related studies. Consider the percentage of articles examining etiology from 1975 to 1980, 1985 to 1990, and 1995 to 2000 in the *American Journal on Mental Retardation*, the main research journal of behavioral work in mental retardation. Even taking a less stringent definition of etiology—any study examining as one of its research groups any organic condition—one sees remarkable change in even the past 20 years. In the late 1970s, 9% of research articles included one or more organic groups (mainly Down syndrome or phenylketonuria). By the late 1980s, this percentage had doubled to 17%, before almost doubling again, to 32%, by the late 1990s (Hodapp, 2004a).

Looked at another way, one could also examine studies on different genetic disorders over time. This time comparing the 1980s to the 1990s, large increases again occur in the number of behavioral research articles on such disorders as Williams, Prader-Willi, Rett, 5p– (Cri-du-chat), and Smith-Magenis syndromes (Figure 6.1, from Hodapp & Dykens, 2004). Examining both organicity in general and individual genetic disorders more specifically, behavioral research has proliferated on genetic mental retardation syndromes during the past 10 to 15 years (Dykens & Hodapp, 2001).

Definition of Behavioral Phenotypes

Given that behavioral research has exploded, how do genetic disorders affect those who have them? We here enter

into the entire question of behavioral phenotypes, a term first used by William Nyhan (1972) over 3 decades ago, but whose definition remains contested to this day.

In its most basic meaning, the term behavioral phenotype highlights the outcomes or phenotypes—in this case, concerning behavior—that result from a particular genotype. Beyond this statement, however, researchers vary. One definition, provided by Flint and Yule (1994, p. 666), states that “a behavioral phenotype should consist of a distinct behavior that occurs in almost every case of a genetic or chromosomal disorder, and rarely (if at all) in other conditions.” This definition thus reserves the term for behaviors that are distinctive, occur commonly among individuals with a genetic syndrome (“in almost every case”), and are unique to a single syndrome (“rarely . . . in other conditions”).

We propose a less stringent definition, but one that may ultimately prove to be more useful for both research and intervention. According to Dykens (1995, p. 523), a behavioral phenotype involves “the heightened probability or likelihood that people with a given syndrome will exhibit certain behavioral and developmental sequelae relative to those without the syndrome.” This second, more probabilistic definition highlights four basic facts:

1. *Many, but not all, individuals with a given syndrome will show the syndrome’s “characteristic” behaviors.* A more probabilistic definition acknowledges the large amount of variance within specific etiologies. Indeed, rarely are etiology-related behaviors found in every person with a particular syndrome. Consider the case of Down syndrome. Even compared to their overall mental ages, children and adults with Down syndrome generally show deficits in linguistic grammar (Chapman & Hesketh, 2000; Fowler, 1990) and often show receptive language abilities in advance of expressive abilities (Miller, 1992, 1999). In addition, approximately 95% of mothers of children with Down syndrome report that others have difficulty understanding their child’s articulation of words and phrases (Kumin, 1994).

Despite such commonly observed deficits, not every person with Down syndrome shows particular difficulties with grammar, articulation, or expressive language. Rondal (1995) recently reported on the case of Françoise, a 32-year-old woman whose IQ is 64. Although Françoise has trisomy 21, she nevertheless utters long and complex sentences. Rondal reports her saying (translated), “And that does not surprise me because dogs are always too warm when they go outside” (“Et ça m’étonné pas parce que les chiens ont toujours trop chaud quand ils vont à la port”;

p. 117). Thus, although grammatical, articulatory, and expressive language problems may be common in Down syndrome, not every person with the syndrome shows such behavioral characteristics.

2. *Some etiology-related behaviors will be unique to a single syndrome, whereas others are common to two or more syndromes.* The second corollary of a more probabilistic definition considers whether an etiology-related distinctive behavior must occur “rarely (if at all) in other conditions.” Recent research strongly implies that etiology-related behaviors are often not unique to a single syndrome.

In fact, connections between genetic syndromes and specific outcomes appear to be of at least two types. The first involves connections that truly are unique, that appear in one and only one genetic syndrome. The second involves connections that are “partially specific” (Hodapp, 1997), in that a few syndromes show a particular behavior that is not generally found in others with intellectual disabilities.

In the first, unique pattern, a genetic syndrome results in a behavioral outcome that is not seen in other genetic disorders. At present, the following behaviors seem unique to one and only one syndrome:

- Extreme hyperphagia (overeating; Dykens, 1999) in Prader-Willi syndrome
- The “cat-cry” (Gersh et al., 1995) in 5p– syndrome
- Extreme self-mutilation (Anderson & Ernst, 1994) in Lesch-Nyhan syndrome
- Stereotypic hand washing or hand-wringing (Van Acker, 1991) in Rett syndrome
- Body self-hugging (Finucane, Konar, Haas-Givler, Kurtz, & Scott, 1994) and putting objects into bodily orifices (Greenburg et al., 1996) in Smith-Magenis syndrome

Obviously, given such a short list, there are probably only a few instances in which a genetic disorder is unique in its behavioral effects. Flint and Yule (1994, p. 667) also noted this peculiarity, nominating as unique (in their term, as examples of a behavioral phenotype) only the self-mutilating behaviors in Lesch-Nyhan syndrome, overeating and abnormal food seeking in Prader-Willi syndrome, and the hand-wringing in Rett syndrome. Although Flint and Yule also propose a few other examples in which a behavior might be unique to one syndrome, such 1:1 relationships are relatively rare.

In contrast, many more instances seem to exist in which partial specificity is at work. To give but a few examples, a particular advantage in simultaneous (i.e., holistic, Gestalt-like) processing compared to sequential (step-by-step) pro-

cessing has now been found in boys with Fragile X syndrome (Burack et al., 1999; Dykens, Hodapp, & Leckman, 1987; Kemper, Hagerman, & Altshul-Stark, 1988) and in children with Prader-Willi syndrome (Dykens, Hodapp, Walsh, & Nash, 1992). Similarly, compared to groups with intellectual disabilities in general, hyperactivity is more frequently found in children with 5p– syndrome (Dykens & Clarke, 1997) and in boys with Fragile X syndrome (Baumgardner, Reiss, Freund, & Abrams, 1995). In both instances, a pattern of strengths and weaknesses or a particular type of maladaptive behavior-psychopathology is found in a few genetic disorders to much greater degree (or in higher percentages of individuals) than is commonly noted among others with mental retardation.

Finally, partially specific behavioral effects seem more in line with many areas of genetics, child psychiatry, and psychiatry. Across these different disciplines, researchers are now discussing the many pathways, both genetic and environmental, by which one comes to have one or another psychiatric disorder. In the terminology of developmental psychopathology, such partially specific pathways involve *equifinality*, the idea that, “in an open system, . . . the same end state may be reached from a variety of different initial conditions and through different processes” (Cicchetti & Rogosch, 1996, p. 597). The clinical geneticist John Opitz (1985, p. 9) put it well when he noted, “The causes are many, but the common developmental pathways are few.”

3. *Etiology-related behaviors occur across many behavioral domains.* Behavioral phenotypes can be found in many different domains. Although much work has centered on maladaptive behaviors common to children with Prader-Willi, Williams, velocardiofacial, and other syndromes (Dykens et al., 2000), many other areas of functioning also show etiology-related behaviors. Thus, in growing numbers of detailed studies of the language of children with Williams syndrome, psycholinguists are gaining insights into whether language is indeed a “modular” system (Fodor, 1983). Such studies compare or correlate levels of functioning across different linguistic and nonlinguistic domains (e.g., Mervis, Morris, Bertrand, & Robinson, 1999). Similarly, various studies have focused on issues pertaining to visuospatial skills in children with Williams syndrome (Belugi, Mills, Jernigan, Hickok, & Galaburda, 1999), jigsaw-puzzle playing in Prader-Willi syndrome (Dykens, 2002), and music in children with Williams syndrome (Lenhoff, 1998). The point is that behavioral phenotypes need not be limited to psychopathology or to any single domain of functioning. Moreover, at times, what is of interest is not a single behavior per se, but a pattern of strengths and weaknesses, connected or disconnected behaviors, or other patterns seen

in one or a few syndromes more often than in others with intellectual disabilities.

4. *A genetic disorder predisposes children to display a particular behavior or set of behaviors, which in turn elicit predictable reactions from others.* Although one generally thinks of behavior as the final outcome of genetic disorders, in many ways the child's behavior constitutes a midpoint in ongoing interactions and transactions with others.

In ongoing work, we have distinguished between direct effects and indirect effects of genetic mental retardation disorders (Hodapp, 1997; Ly & Hodapp, in press). Direct effects relate to the child's behaviors; genetic disorders predispose children and adults who have them to show specific, etiology-related patterns of strengths and weaknesses, developmental trajectories, and specific maladaptive behaviors and personalities. Indirect behaviors, in contrast, involve the effects that such behavioral characteristics have on others (Hodapp, 1999). To complicate matters, parental, sibling, teacher, and peer reactions and behaviors (indirect effects) can then feed back onto children themselves, helping to reinforce, extinguish, or modify the original behavior.

In recent years, we have been impressed by both the nature and complexity of such indirect effects. As we demonstrate later, children with different genetic disorders elicit behaviors from surrounding individuals partly based on their own etiology-related behaviors, and partly based on the meaning of their specific syndrome to parents and families. In addition, the child's behavior may not be the sole personal characteristic that elicits reactions and behaviors from others, and parental behaviors may operate differently in different contexts, tasks, and situations. We have barely begun to understand how, when, and why children with different genetic syndromes affect people in their surrounding environments.

ORGANISMIC ISSUES

Given the shift from examining "children with mental retardation" to examining "children with a specific syndrome," all discussions of organismic, and even of contextual, development must now occur on three distinct levels. One thus asks whether patterns of development seen in typically developing children are also seen in children with mental retardation more generally, in children with organic versus cultural-familial mental retardation, and in children with different genetic (or other organic) syndromes. We use this three-level approach to highlight issues concerning developmental sequences and cross-domain relations, the two main organismic issues. As noted subsequently, new

findings are changing the ways that these two venerable developmental topics are being conceptualized.

Similar Sequences

As briefly noted earlier, Zigler's (1967, 1969) developmental approach to mental retardation began with two hypotheses. With regard to the similar-sequence hypothesis, Zigler (1967) hypothesized that children with (cultural-familial) mental retardation would develop in the usual or normative sequences of development. Generally, the idea of similar sequences involves a clear, specifiable order to developmental attainments, measures of sequential development over time or cross-sectionally, and sequential development within a single domain. We first discuss these several subparts.

Clear, Specifiable Order to Developmental Attainments

By necessity, sequences must be clear and specifiable. The theorist must state what, exactly, is the behavior of interest, explaining what does and does not qualify for the child to be considered to have attained a specific stage or substage. In the object permanence subdomain of Piagetian sensorimotor stages, for example, behaviors specifically involve the child uncovering an object under 1 versus 3 cloths, first with visible and then with invisible displacement, and specifications as to how often such behaviors must occur (e.g., 1 out of 2 trials; Dunst, 1980; Uzgis & Hunt, 1975).

In the same way, the sequence or ordering itself must be specified. The child in the earliest step or substep will be able to recognize an entire object from seeing only a part of that object. In contrast, at a higher level, the child will retrieve a partially hidden object, then a totally hidden object, then an object hidden under more than one screen, and finally an object hidden invisibly (within the experimenter's hand) under one of the three screens. In short, the progression from Step 1 to Step 2 to Step 3 to Step 4 is clear and testable.

Over Time or Cross-Sectional Indicators

Strictly speaking, sequences only appear over time. To continue with the object permanence example, a typically developing child of 4 months would be expected to identify a bottle in which the nipple was turned away, but to be able to perform no other tasks. A few weeks or months later, the child would be able to perform the easier task, but now might also be able to retrieve an object hidden under one cloth. Later still, the two easier tasks would be performed,

but the child would also be able to retrieve an object hidden under three cloths, with invisible displacements.

Though normative developmental sequences are best examined longitudinally, attempts have been made to examine sequences cross-sectionally. Such tests can be performed in several ways. One test involves order-of-difficulty examinations (Weisz, Yeates, & Zigler, 1982). Consider three groups of typically developing children, ages 8 months, 12 months, and 16 months. According to Piaget's theory, most 8-month-olds should be able to retrieve an object that was partially hidden, fewer would find an object hidden under a single screen, and almost none would be able to find an object hidden under three screens. Among the 12-month-olds, all should be able to find partially hidden objects, most should be able to retrieve an object under a single screen, and a few might even be able to solve the 3-screen task. Finally, 16-month-olds should all be able to solve the first two problems, and most should be able to retrieve an object hidden under three screens.

In addition to using three groups to demonstrate sequential development, similar findings can be noted using diverse groups of children at different ages. Here one relies on Guttman scaling (Green, 1956; Guttman, 1950), along with recent modifications and extensions (e.g., Rasch modeling; see Dawson, 2002, for a reanalysis of Kohlberg's moral reasoning tasks). The idea, now applied to each single child, is that, if three different tasks occur in a set sequence, and if lower-order tasks do not drop out when higher-level tasks come in, then the child should show sequential ordering of difficulty. Thus, if tasks occur in a 1, 2, 3 order, then a child might pass item 1 but not 2 and 3, or pass 1 and 2 but not 3, or pass or fail all three items. Rarely, if ever, should a child pass item 2 but fail item 1, or pass 3 and fail either item 1 or item 2.

Within a Single Domain

A final issue, that sequences occur within a specific domain or even subdomain, is not so often noted. To Piaget, cognition during infancy can be divided into such subdomains as object permanence, causality, symbolic play, means-ends relations, and vocal and gestural imitation. Later sensorimotor scales were used to examine sequential development within each of these different subdomains separately.

But what constitutes a single subdomain of intellectual functioning is not so obvious. Simply stated, it is not always clear which particular behaviors constitute an underlying "skills family." For example, most early language researchers would consider early hand gestures, such as pointing or showing, as evidence of the same early commu-

nicative skills that will later result in spoken language. Other domains of cognition or language may also exist.

Similar Sequence Findings

This background into sequential development helps frame the similar-sequence findings. Until recently, the findings related to the similar-sequence hypothesis appeared clear-cut. Looking at most domains and subdomains, children with mental retardation follow, in order, the usual or normative sequences of development (Weisz & Zigler, 1979). Moving to the two groups of children with organic and cultural-familial mental retardation, this statement still mostly holds. One possible exception might involve children with severe seizure disorders, but here difficulties arise in relation to what constitutes a valid test of these children's abilities. Children with mental retardation may also become less systematic or differently sequential when tasks are more social, or occur later in development, as opposed to these children's usual invariant sequential developments on earlier and less social tasks (Hodapp, 1990).

But the issue becomes more interesting when one considers specific etiological groups. Children with Down syndrome, the most studied group, usually follow the hypothesized normative sequences (Cicchetti & Beeghly, 1990; Dunst, 1990), but other differences may arise. Specifically, Dunst (1990) and Wishart and Duffy (1990) noted an increased "fragility" of development among children with Down syndrome, such that a "2 steps forward, 1 step backward" pattern seems more likely to hold. Some even question whether the fragility of development in Down syndrome extends beyond greater numbers of regressions per se, as children do not always show patterns of failing the highest stage earlier achieved (Morss, 1983).

But the most intriguing findings concern the early communicative development of children with Williams syndrome. In most typically developing children, gestural communication, what Bates, Camaioni, and Volterra (1975) call "proto-declaratives" and "proto-imperatives," occur prior to verbal expression of words per se. But Mervis, Robinson, Rowe, Becerra, and Klein-Tasman (2003) reported that this sequence of pointing before speaking was not found in 9 of 10 children with Williams syndrome. On average, these 9 children with Williams syndrome produced referential object labels ("ball") 6 months before beginning to comprehend or produce referential pointing gestures. Although this finding makes sense given the intellectual profiles shown by most children with William syndrome (discussed later), such findings nevertheless have many theoretical and practical implications.

Cross-Domain Relations

The second of Zigler's developmental predictions concerned the structuring of development from one domain to another. According to the similar-structure hypothesis, when matched on overall mental age to nonretarded children, children with mental retardation should perform similarly on a specific cognitive or linguistic task. For example, groups matched on overall mental age (i.e., MA matches) should perform similarly on linguistic, attentional, or other cognitive-linguistic tasks. In essence, there should be no outstanding strengths or weaknesses in the intellectual abilities of children with mental retardation; these children should be developing at a slower rate than nonretarded children, but their developmental profiles should be flat or even.

Historically, the similar-structure hypothesis has two sources, one explicit and one implicit. Explicitly, Zigler was arguing against those who theorized many defects in mental retardation. He argued that, if children with cultural-familial retardation did not have any single defect causing their mental retardation, then they should show MA-level performances on Zeaman and House's attentional, Luria's language mediational, or Ellis's stimulus trace tasks. Zigler has long been criticized for arguing that "no differences" findings support the similar-structure position (Spitz, 1983); technically, when two groups do not differ statistically, one can state only that they do not differ, not that their performances are necessarily the same (see also Weisz et al., 1982). Such studies do imply, however, that no single skill appears as a deficit below the child's overall level of mental age. By inference, no single deficit seems to be causing the child's mental retardation. Such reasoning led to Zigler's adherence of MA matches in retarded-nonretarded comparisons of intellectual or linguistic functioning.

Implicitly, Zigler was also influenced by Piaget's horizontal stage notion of development. If children with cultural-familial mental retardation develop like nonretarded children, then they, too, should show identical or near-identical level functioning across various cognitive tasks, as Piaget proposed (Kessen, 1962). Although such views of Piagetian structures have since been criticized (Fodor, 1983; Gardner, 1983), Zigler implicitly followed the idea of horizontally organized developments in his theorizing about children with cultural-familial mental retardation.

Findings

Findings seem fairly clear for the similar-structure hypothesis. The similar-structure hypothesis holds up reasonably

well for children with cultural-familial mental retardation, although even here children display performance that is below overall MA levels on some information-processing tasks (Weiss et al., 1986). Less clear is why such lower-than-expected functioning occurs. Some researchers have postulated that children with cultural-familial mental retardation really do have a deficit in their information-processing abilities (Mundy & Kasari, 1990); conversely, any seeming deficit may be due more to the boring, repetitive nature of many information-processing tasks (Weisz, 1990) or other motivational factors such as outerdirectedness (Bybee & Zigler, 1998). In contrast, all would agree that children with organic mental retardation show performance on several cognitive-linguistic tasks that falls below their overall mental ages.

Again, the most discrepant findings relate to specific genetic mental retardation disorders. Over the past 10 to 15 years, a variety of etiology-related strengths-weaknesses have been noted in different genetic mental retardation disorders. Some of these findings concern different aspects of intellectual functioning. Findings of this sort include the simultaneous-over-sequential processing results for boys with Fragile X syndrome and for individuals of both genders with Prader-Willi syndrome. Other strengths-weaknesses relate across tests, for example, the many findings of language-over-visuospatial abilities among children with Williams syndrome (Mervis et al., 1999). See Table 6.1 for a description of several of the more striking cognitive-linguistic strengths and weaknesses in several etiological groups.

Remaining Issues

Recent etiologically related findings of strengths and weakness are intriguing for a variety of reasons. To families and teachers of children with different syndromes, these profiles of development may lead to more targeted programs of intervention (Hodapp & Fidler, 1999). But etiology-related profiles also relate to critical developmental questions, a few of which we describe next.

What Are the Connections (or Disconnections) across Various Domains of Functioning? Here, the recent (and many ongoing) studies of children with Williams syndrome are most instructive. Particularly in earlier studies, language functioning was thought to be modular in Williams syndrome. Modularity, in Fodor's (1983) sense, refers to an encapsulated system that develops with little or no contact with other elements of the child's development (see also Gardner's, 1983, multiple intelligences). Given the high-level language abilities of some children with

TABLE 6.1 Prominent Genetic Forms of Mental Retardation

Disorder	Genetics	Prevalence	Prominent Behavioral Features
Down syndrome	95% involve trisomy 21	1–1.5/1,000 live births	Moderate MR; social strengths; weaknesses in grammar and speech; relative strengths in auditory versus visual short-term memory
Prader-Willi syndrome	66% involve deletions on chromosome 15, now known to be of two types; remainder involve maternal disomy	1/15,000 live births	Mild MR; proneness to obesity, food foraging, and preoccupations; stubbornness and obsessive-compulsive behaviors; visuospatial strengths (especially in jigsaw puzzles)
Williams syndrome	Microdeletion on chromosome 7	1/20,000 live births	Mild MR; high levels of sociability; relatively strong language skills and weak visuospatial skills; hyperacusis; high levels of fearfulness and anxiety

Williams syndrome, a strong case for modularity of language seemed to have been made.

In recent years, however, the picture has changed markedly. The main issue here concerns strengths and weaknesses, which obviously occur, and the degree to which a “strong area” is connected to a “weak area.” If modularity truly holds, few connections should obtain; if the areas are linked, then we have evidence of specific strengths and weaknesses, but not of modularity per se. This latter conclusion seems most likely. Unlike what would be predicted from a modular perspective, Mervis et al. (1999) found strong correlations (from .47 to .64) between various measures of short-term memory and grammatical levels. Although language is relatively strong and visuospatial skills weak in children with Williams syndrome, these children’s language is also not totally modular. In line with typically developing children, language in children with Williams syndrome connects to other areas of these children’s cognition.

How and Why Do Various Strengths and Weaknesses Develop? A second issue concerns the development of these various strengths and weaknesses over time. Obviously, etiology-related strengths and weaknesses do not appear fully formed at birth; no child with Williams syndrome has perfect language at birth, no child with any other syndrome shows such pronounced patterns of strengths and weaknesses, fully formed, at birth. But how such strengths and weaknesses appear has only begun to be examined. During the past few years, several researchers have examined cognitive-linguistic profiles over time in children with several different etiologies of mental retardation. Most studies have been cross-sectional, although a few recent studies have examined evolving profiles as the child develops.

Across several etiological groups, with increasing chronological age the children’s strengths develop more

quickly than do their weaknesses. In Down syndrome, the pattern of visual-over-auditory short-term memory becomes more pronounced during the late teen years (Hodapp & Ricci, 2002), and, among boys with Fragile X syndrome, the advantage of simultaneous-over-sequential processing also becomes more pronounced as these children get older (Hodapp, Dykens, Ort, Zelinsky, & Leckman, 1991). In the sole longitudinal study, Jarrold, Baddeley, Hewes, and Phillips (2001) examined children with Williams syndrome to determine the development of vocabulary (a relative strength in this syndrome) versus visuospatial skills (a relative weakness). Examining 15 children and adolescents on six occasions over a 4-year period, Jarrold et al. found that vocabulary levels developed much more quickly over time than did visuospatial skills. Such divergent trajectories allow already existing relative strengths to become gradually stronger and relative weaknesses gradually weaker as these children get older.

Although no good explanations exist as to why strengths become stronger and weaknesses weaker over time, one possibility involves an interplay between etiology-related propensities and subsequent experiences. One measure of experience involves the child’s everyday, leisure-time activities, that is, those behaviors that children (or their parents) choose to perform every day. In one study, Rosner, Hodapp, Fidler, Sagun, and Dykens (2004) examined the everyday leisure activities of three groups of children: those with Williams syndrome, with Prader-Willi syndrome, and with Down syndrome. Using parent reports of leisure-time behavior from Achenbach’s (1991) Child Behavior Checklist, behaviors were grouped into those involving music, reading, visual-motor activities, athletics, pretend play, and focused interests.

The findings mostly reflect etiology-related strengths and weaknesses. In line with their excellent skills in jigsaw puzzles, 50% of children with Prader-Willi syndrome played with jigsaw puzzles, whereas only 9% and 2%, re-

spectively, of persons with Down syndrome and Williams syndrome engaged in this activity. Conversely, in line with their visuospatial weaknesses, children with Williams syndrome did not engage in visuospatial activities. In the overall category of visual-motor activities, only 31% of those with Williams syndrome participated in any visual-motor activities, compared to 76% and 60% of persons with Prader-Willi and Down syndromes, respectively. Specific behaviors like arts-and-crafts activities were listed for 35% of the group with Down syndrome and for 30% of individuals with Prader-Willi syndrome, but for only 7% of those with Williams syndrome. Persons with Williams syndrome (or their parents) seem to avoid activities that these children may find difficult to perform.

Our suspicion is that genetic etiologies predispose children to particular cognitive-linguistic profiles, but that these profiles then become more pronounced due to the child's ongoing experiences. For most syndromes, the degree of difference between levels of strong versus weak areas is probably relatively small during the early years. As children more often perform activities in strong areas and avoid activities in weaker areas, however, increasing discrepancies arise. A snowball effect may thus result from the interplay of the child's etiology-related propensities and the child's ongoing transactions with the environment. Such views also seem consonant with the late-appearing gestures (as opposed to verbal labels) in the early communication of children with Williams syndrome (Mervis et al., 2003).

This perspective also seems in line with the notion that behavioral phenotypes are best conceptualized within a dynamic, developmental framework. To quote Karmiloff-Smith and Thomas (2003, p. 980), "More complex cognitive structure = less complex structure \times process of development." In essence, then, Williams syndrome, like all genetic disorders, simply sets the stage for later interactions-transactions with the environment over time. But exactly how such interplays proceed—and their effects on the child's developing brain—must remain open at present.

What Is the Relationship between Similar Sequences and Cross-Domain Profiles? When describing the similar-sequence hypothesis, we noted that sequences were generally considered within single domains or subdomains. Thus, one examined sequences within object permanence or among early communicative development. The idea of strong and weak areas did not enter in.

Given recent findings, however, it becomes necessary to link sequences and cross-domain relations. Consider the finding that children with Williams syndrome do not show

the sequence of communicative gestures before verbal words. Examined only as an example of the similar-sequence hypothesis (without reference to the usual Williams syndrome profile of cognitive-linguistic strengths and weaknesses), one simply reports an example of nonnormative sequences. By joining both sequences and cross-domain profiles, however, one sees the influence of etiology-related strengths-weaknesses even on sequences within a single domain or subdomain. In this case, children with Williams syndrome show particular difficulties on many visual-spatial tasks. Even in infancy, then, they seem to have difficulty in gestures, even those (such as pointing and showing) that relate to early communication. For our purposes, it now seems necessary to link sequences, which have always been considered within a single domain, and cross-domain relations. The two seem related, and it is likely that, once one knows the specific strengths and weaknesses demonstrated by several different etiological groups, one might almost be able to predict examples in which most children with a particular syndrome might be likely *not* to show the usual or normative sequences of development.

Summary

Although questions of sequences and cross-domain organization pervade developmental work over many decades, our understandings of these issues have advanced greatly over the past decade. Even until the year 2000, the similar-sequence finding held for most conditions and developmental sequences. Only recently have several nonnormative sequences been noted, complicating the idea that development in children with mental retardation is merely slowed compared to typically developing children. Similarly, with respect to cross-domain relations, recent findings highlight which particular domains within which particular etiologies are relative strengths or weaknesses. Even more recent work begins to document that etiology-related strengths and weaknesses become more pronounced with age and, in a preliminary way, explains why such intensifications of cognitive-intellectual profiles might occur.

Finally, sequences and structures need to be examined within a single conceptual framework. Though their connections might seem obvious, similar-sequence and similar-structure studies have, until now, generally proceeded in isolation one from another. But if indeed nonnormative sequences most often occur within weak areas of functioning, we begin to see how the two interrelate. Remaining to be examined are the implications of this basic interrelationship for interventions and for better understandings of cross-domain relations and sequential developments. Given

the new studies of behavioral development in many different etiological groups, we are only now truly understanding sequences and structures.

CONTEXTUAL DEVELOPMENT

Compared to sequences and structures of children's own development, the contexts in which children with mental retardation develop have been studied for a much shorter time. This relatively short research history reflects relations between developmental psychology proper and developmental approaches to mental retardation.

To provide a brief history, Zigler (1967, 1969) formalized the developmental approach to mental retardation in the late 1960s. With Weisz in the 1970s and with Cicchetti, Beeghly, Pogge-Hesse, Hodapp, and Burack from the 1980s on, that approach was tested, applied to new (mostly organic) populations, and updated. The updates from the 1980s informed traditional issues of sequences and structures but also capitalized on newer work in the wider field of developmental psychology. Bell's (1968) work on interactionism and mother-child interactions, Sameroff and Chandler's (1975) transactional model, and Bronfenbrenner's (1979) ecology of childhood all began to be included in developmental approaches, in preliminary form during the 1980s (Zigler & Hodapp, 1986), with more elaboration during the 1990s (Burack, Hodapp, & Zigler, 1998; Hodapp, 1998; Hodapp & Zigler, 1995).

Four Preliminary Issues

Other background issues go beyond the history of developmental approaches to mental retardation per se. Before discussing mother-child interactions and families of children with disabilities, we first note four preliminary issues that frame such topics.

Subject Groups

Just as in studies of children themselves, studies of parents and families must be evaluated based on who is being studied. Does a particular study examine parents or families of children with disabilities, of children with mental retardation, or of children with a particular syndrome? As before, many more studies exist concerning either parents-families of children with disabilities or with mental retardation in general; fewer focus on children with a specific genetic

syndrome (usually Down syndrome) or psychiatric disorder (usually Autism).

But as we are increasingly appreciating, differences may arise depending on which parents or families one examines. Parents and families overall react differently to children with one versus another genetic mental retardation syndrome. Such reactions relate to the child's personality and maladaptive behavior or, in certain circumstances, to the child's actual or perceived cognitive-linguistic strengths and weaknesses. Further complications may also relate to the child's age and the parents' knowledge of etiology-related behaviors. Different findings may occur when one is examining parents or families of children with mental retardation compared to parents-families of children with one or another particular genetic syndrome (Seltzer, Abbeduto, Krauss, Greenberg, & Swe, 2004).

Same but Different Sets of Parental-Familial Needs

Parents and families of children with disabilities have some needs in common and some that differ from those of parents-families of typically developing children. On one hand, the needs of the two groups are similar. Both sets of parents need to provide for and socialize their children, promote their children's development, and launch their adolescents into (hopefully successful) adult lives. At the same time, these families face reactions and needs that are specific to parents and families of children with disabilities. In contrast to parents of typically developing children, parents of children with disabilities need to learn about the many support services available in their community; about the many legal rights, hearings, and appeals that surround educational and other services; and about detailed aspects of the services themselves, the individualized family service plans (IFSPs) during preschool, individualized educational plans (IEPs) during school years, and individualized transition plans (ITPs) during the transition from adolescence to adulthood.

Parents of children with specific genetic syndromes have other, more specialized needs. These needs relate to learning about their child's specific condition, about which professionals, centers, schools, group homes, or respite care settings might be most helpful, and about parent groups specific to their child's disability. Parent needs therefore exist on three levels: as parents of any child, as parents of a child with disabilities, and as parents of a child with a specific disability condition.

Cutting across these differing needs are both formal (professional) and informal (nonprofessional) support systems. To most family researchers, support can be divided

into three types (e.g., Kazak, 1987). First, *emotional support* helps parents and other family members come to terms with the strong emotional reactions that accompany raising a child with disabilities. Second, *informational support* involves gaining knowledge about the child, the child's condition, necessary services, and treatment options available in one's own local community. Third, *tangible support* concerns money, interventions, and the performance of such day-to-day tasks as providing babysitting or respite care or driving the child to out-of-home-based therapy. Each type of support is important, and each is probably needed by most parents some of the time.

Changing Perspectives toward Families in the Disabilities Field

In developmental psychology, studies are relatively new of families, mother-child interaction, and the larger ecology of childhood. Depending on the specific topic, such studies date to the early to late 1970s. In contrast, families of children with disabilities have been examined for over 100 years (Blacher & Baker, 2002), with more sustained research attention over the past 40. But even from about 1960 on, such history has changed dramatically.

Most early studies considered only the negative consequences that may arise from parenting a child with disabilities. Using Freud's (1917/1957) model of mourning in response to losses of any kind, Solnit and Stark (1961) described what they called "maternal mourning." On the birth of a child with disabilities, mothers mourn, as in a death, the loss of the idealized, perfect child. Mothers were thought to experience grieving that was characterized by a specific, stage-like process (see Blacher, 1984). Following Solnit and Stark, family studies of the 1960s and 1970s then focused on depression, neuroticism, role tensions, and other adverse psychological effects. Some researchers examined depression in mothers (Cummings, Bayley, & Rie, 1966; Friedrich & Friedrich, 1981) and in fathers (Cummings, 1976). Others studied siblings, noting that the oldest nondisabled daughters may be most at risk for psychological problems due to increased household or child care responsibilities (Lobato, 1983). The general conclusion was that bad things happen to families of children with disabilities.

Beginning in the early 1980s, researchers began to adopt a more balanced view of these families. In 1983, Crnic, Friedrich, and Greenberg proposed that, instead of necessarily negative or pathological outcomes, the outcomes arising from parenting a child with disabilities might better be construed in terms of stress and coping. In stress-and-

coping models, the child with disabilities is considered an increased stressor on the family, but one that different parents and families handle differently. Parenting the child with disabilities thus became akin to handling any stressor, such as coping with the illness of a parent or child, or losing a job, or moving. Like reactions to all stressors, parents and families can react either positively or negatively.

This shift from negative-pathological to stress-and-coping models had several effects on subsequent research. The main effect was a more positive view. Parents and families of children with disabilities were no longer thought to always be negatively affected, although they could be. Instead, researchers began to search for risk and protective factors within children, parents, and families (Hodapp, 2002).

Secular Changes toward Children with Disabilities and Their Families

At the same time as disability professionals changed their conceptualizations of these parents and families, parallel changes occurred in society at large (Glidden, 2002). Consider where and how children with disabilities live. In the mid- to late 1960s, many more persons, including children, resided in large, often impersonal institutions. In 1967, almost 200,000 Americans lived in institutions, including 91,000 children. By 1997, that number had fallen to 56,161, including fewer than 3,000 children (Anderson, Lakin, Mangan, & Prouty, 1998; Lakin, Prouty, Braddock, & Anderson, 1997). Of those children who remained at home during the 1960s and early 1970s, access to formal education varied widely, depending mainly on the generosity of their particular town or state. Only in 1974, with the passage of the federal Education for All Handicapped Children Act (PL 94-142), were U.S. states and towns required to provide a "free, appropriate public education" to all students, including those with disabilities (see Hallahan & Kauffman, 2002).

Over these past few decades, services have also extended beyond simply schooling. Across the United States, states now provide early intervention services during the 0- to 3-year period. Later, after the school-age years, transition and adult services help young adults with disabilities to work and live as independently as possible (Wehman, 2001). Services for individuals and their families are thus lifelong, and one must consider the interplay between children-parents-families and the service-delivery system from a life span perspective.

Beyond the presence of services themselves, one must consider how such services are conceptualized. Partly due

to the change from pathological to stress-and-coping models, service delivery is now considered in terms of supporting families. Instead of being conceptualized as patients who need to be cured, today's parents, siblings, and families are conceptualized as consumers of services who require different sets of long- or short-term support to cope more effectively. This "support revolution" has changed the nature of services and how such services are understood by families and professionals (Hallahan & Kauffman, 2002).

Mother-Child Interactions

These four issues, then, frame our examinations of contextual issues related to children with disabilities. As in our discussions of organismic developmental topics, we again highlight two issues: mother-child interactions and family coping. Here again we focus on more general findings relating to parents-families of children with disabilities as well as on newer work examining both interactions and family reactions concerning children with different genetic disorders.

Studies of Mothers and Children with Mental Retardation

Owing much to Bell's (1968) interactionism, in the early 1970s researchers began to examine mother-child interactions when children had mental retardation. The initial question was one of "same or different": Were mothers' behaviors toward their child with mental retardation the same as or different from maternal behaviors to typically developing children?

Such differences were found in most early studies. Buium, Rynders, and Turnure (1974) and Marshall, Hegrenes, and Goldstein (1973) found that mothers of children with Down syndrome provided less complex verbal input and were more controlling in their interactive style than were mothers of same-age nonretarded children. Although these authors noted only that the two groups of mothers differed in their behaviors, later workers citing these studies referred to the "verbal deprivation" (Mahoney, 1975) encountered by children with mental retardation.

But not all studies found such differences in maternal input. Rondal (1977) and Buckhalt, Rutherford, and Goldberg (1978) observed that mothers of children with mental retardation behaved similarly to mothers of nonretarded children. Rondal noted that, when children with Down syndrome and nonretarded children were matched on the child's mean length of utterance (MLU), "None of the comparisons of mothers' speech to normal and to Down

Syndrome children led to differences that were significant or close to significant" (p. 242) between the two groups. Additionally, both groups of mothers adjusted their language upward (e.g., longer MLUs) as the children's language level increased. Rondal concluded, "The maternal linguistic environment of DS children between MLU 1 and 3 is an appropriate one" (p. 242).

In reconciling such divergent findings, most differences across studies seem to be due to methodological differences. In general, when children with mental retardation were matched to nonretarded children on chronological age (CA), mothers of children with mental retardation interacted differently. But children with mental retardation are, by definition, functioning at levels below nonretarded age-mates; CA matching may thus be inappropriate. A more appropriate strategy might be to match mother-child dyads on the child's mental age (MA) or the child's level of language (MLU).

An additional issue concerns the focus of the interaction. Although mothers of children with mental retardation are equivalent to mothers of typically developing, MA- (or MLU-) matched children on their levels of linguistic input, such is usually not the case when maternal style is examined. Compared to mothers of typically developing children, mothers of children with mental retardation are often found to be more didactic, directive, and intrusive (Marfo, 1990). Such stylistic differences between mothers of children with and without mental retardation are seen on a number of levels. Tannock (1988) found that, compared to mothers of nonretarded children, mothers of children with Down syndrome took interactive turns that were longer and more frequent; in addition, these mothers more often "clashed," or spoke at the same time as their children (also Vietze, Abernathy, Ashe, & Faulstich, 1978). These mothers also switched the topic of conversation more often, and less often silently responded to the child's utterance.

Although this stylistic difference has since been noted in many studies, why mothers in the two groups differ remains unclear. The most common explanation is that mothers of children with mental retardation inject their parenting concerns into the interactive session. Greater numbers of mothers of children with mental retardation consider interactions as "teaching sessions," as moments not to be squandered in the nonstop effort to intervene effectively (Cardoso-Martins & Mervis, 1984; Jones, 1980). In contrast, mothers of typically developing children display fewer fears and concerns; they may simply desire to play—in a more spontaneous, less directive manner—with their typically developing children.

Studies of Mothers and Children with Specific Genetic Etiologies

Over the past decade, studies began to examine mother-child interactions when children have different genetic etiologies. Following from the indirect effects model described earlier (Hodapp, 1999), the question concerns how different genetic disorders lead to different child behaviors, which in turn lead to different maternal reactions.

To date, two sets of studies show such etiology-related differences in maternal behaviors. The first concerns children with Down syndrome and so-called dependency cues. To simplify somewhat, compared to children with mental retardation overall, children with Down syndrome have long been considered to have upbeat, sociable personalities (Carr, 1995; Hornby, 1995) and to show lesser amounts of maladaptive behavior-psychopathology (Dykens & Kasari, 1997; Meyers & Pueschel, 1991). But these children may also have other characteristics that lead others to want to nurture them. Compared to typical children of the same chronological age, children with Down syndrome generally display more infantile, "babylike" faces (Allanson, O'Hara, Farkas, & Nair, 1993). As Zebrowitz (1997) showed, adults perceive babyfaced (as opposed to more "adult-faced") individuals as more sociable, warmer, dependent, naïve, and compliant. In one study in which naïve adults rated children's faces, adults perceived children with Down syndrome (compared to children with other types of mental retardation) as more dependent, babylike, and warmer (Fidler & Hodapp, 1999).

In further work, Fidler (2003) examined the nature of maternal vocalizations—so-called motherese—provided to children with Down syndrome. As one might expect when interacting with more immature, dependent-looking children, mothers gave more high-pitched and variably pitched intonation patterns in interactions with their children with Down syndrome than to children with mixed mental retardation of similar mental ages. Although it remains unclear what exactly mothers were reacting to (the child's personality, lack of psychopathology, or facial appearance), mothers of children with Down syndrome nevertheless showed differences in their interactive behaviors compared to mothers of children with other types of mental retardation.

A second set of studies relates to mothers' reactions to their child's cognitive strengths and weaknesses. In one study, Ly and Hodapp (in press) examined child effects on parents' behaviors in parent-child dyads of children with Prader-Willi syndrome versus with Williams syndrome. These two groups were chosen due to the fact that children with Prader-Willi syndrome are, on average, particularly

proficient in jigsaw puzzles (Dykens, 2002). In contrast, children with Williams syndrome are generally deficient in a wide variety of visual-spatial skills (including jigsaw puzzles). In a short parent-child interaction, Ly and Hodapp measured parents' amount of helping and reinforcement behaviors in response to interacting with their child to complete a jigsaw puzzle task. From attribution theory (Graham, 1991), parents of children with Williams syndrome (versus with Prader-Willi syndrome) were hypothesized to provide more help and reinforcement during the jigsaw puzzle interaction task.

Compared to parents of children with Prader-Willi syndrome, parents of children with Williams syndrome provided more helping and more reinforcement behaviors. Within the 5-minute interaction session, parents of children with Williams syndrome helped their child 49 times, compared to slightly fewer than 24 times for the Prader-Willi parents. Similarly, parents of children with Williams syndrome reinforced their children over twice as often as did parents of children with Prader-Willi syndrome (means = 14.14 and 5.75, respectively). Further analyses showed that both the child's level of puzzle abilities and the specific etiology (and, presumably, the mother's sense of what her child with Williams or Prader-Willi syndrome "should do") both contributed to these between-group differences in maternal interactive behaviors.

These findings indicate that different genetic mental retardation syndromes may have indirect effects on parents. If parents of children with Down syndrome react to their child's more pleasant personality, lack of maladaptive behavior, and babylike facial appearance, and those of children with Prader-Willi and Williams syndromes react to high versus low puzzle abilities (respectively), then different genetic disorders may indirectly affect surrounding adults.

Families

More than most areas of mental retardation work, family research has been affected by changing perspectives over the past 20 years. In contrast to the more negative, pathological view held by professionals a few decades ago, researchers now conceptualize families of children with mental retardation more from stress-and-coping perspectives. This change has led to new theoretical models, studies of families of children with specific etiologies, and approaches in how research is performed.

Theoretical Models

The shift from negative-pathological to stress-and-coping perspectives has spurred new models that emphasize

heterogeneity from one family to another. Consider the so-called Double ABCX model (Minnes, 1988; adapted from McCubbin & Patterson's, 1983, ABCX model). According to the Double ABCX model, the effects of the "crisis" of having a child with retardation (X in the model) is due to specific characteristics of the child (the "stressor event," or A), mediated by the family's internal and external resources (B) and by the family's perceptions of the child (C). But because children with mental retardation and their effects on families change over time, the term "Double" has been applied to the original ABCX model. The Double emphasizes that characteristics of the child change as the child gets older, the family's internal and external resources may change, and changes may occur in the family's perceptions of the child.

Although overly broad, the Double ABCX framework has nevertheless served researchers well. In its most general sense, the model helps explain both negative and positive consequences of rearing a child with mental retardation (Minnes, 1988). For all families, children who display fewer emotional problems and require less physical caretaking may help parents and families to adjust more positively. In the same way, families with few internal or external resources are more likely to be negatively affected by the child with retardation; families with more resources should do better.

Two elements of the model have been particularly informative. The first pertains to parents' internal and external resources, the B term of the Double ABCX model. Parents who take a more active, problem-solving approach to rearing their child with disabilities experience less depression than "emotion-based" copers (i.e., those who either dwell on or, conversely, deny all emotions; Essex, Seltzer, & Krauss, 1999; Seltzer, Greenberg, & Krauss, 1995; Turnbull et al., 1993). Similarly, parents with larger, more effective support systems do better. To take the most obvious examples, mothers in good versus bad marriages cope better, as do parents in two-parent versus one-parent families, and those at higher socioeconomic levels (see Shapiro, Blacher, & Lopez, 1998, for a review).

Second, children's own characteristics (A of the Double ABCX model) may elicit better or worse coping from their families. Children who are more dependent on their parents, as well as those showing a lack of social responsiveness, unusual caregiving demands, or aggressiveness, are most problematic for parents (Beckman, 1983; Frey, Greenberg, & Fewell, 1989; Minnes, 1988). Moreover, the direction of effects likely runs from child behavior to parent reaction. Keogh, Garnier, Bernheimer, and Gallimore (2000) examined families when the children with disabilities were 3, 7,

and 11 years old. Using path analyses, they showed that the child's higher levels of behavior problems, greater degrees of cognitive impairment, and lower levels of personal-social competence affected parent and family adaptation. In contrast, parental changes and adaptations of the family routine usually did not influence later child behaviors.

Etiology-Related Studies

Similar to research on parent-child interactions, family work focusing on different genetic syndromes is relatively new. The single exception is Down syndrome, a group of families that have been examined over many years. To date, many findings of etiology-related family work reinforce earlier work that examined families of children with mixed or heterogeneous forms of mental retardation. But, as we illustrate, the potential of examining families of children with specific genetic disorders goes beyond mere replication.

So far, several studies have examined the stress levels of children with different genetic forms of mental retardation. Some studies have examined a single etiological group, and others have compared two or more groups. As when families of children with mixed or heterogeneous mental retardation have been examined, these studies find that children with different genetic etiologies also cause greater levels of parental stress when children show higher levels of maladaptive behaviors (Hodapp, Dykens, & Masino, 1997; Hodapp, Wijma, & Masino, 1997).

But beyond this connection between the child's maladaptive behavior and parental stress, other, more intriguing effects of etiology have also been noted. Consider the so-called Down syndrome advantage (Seltzer & Ryff, 1994). Parents of children with Down syndrome generally report less stress compared to parents of children with Autism or with other types of mental retardation. Comparing to same-age children with Autism, Holroyd and MacArthur (1976) found that parents of children with Down syndrome reported less stress overall, and Kasari and Sigman (1997) found that parents of children with Down syndrome versus with Autism reported less child-related stress. Sanders and Morgan (1997) found that both mothers and fathers of children with Down syndrome versus with Autism experienced similar levels of parental pessimism but fewer parent and family problems.

Other studies compared stress levels in parents of children with Down syndrome to levels in parents of children and adults with other types of mental retardation. Fidler, Hodapp, and Dykens (2000) found that parents of 3- to 10-year-old children with Down syndrome reported less stress relative to parents of children with Williams syndrome or

Smith-Magenis syndrome. In a study comparing mothers of children with heterogeneous causes of mental retardation, mothers of children with Down syndrome reported lower total child-related stress levels (Hodapp, Ricci, Ly, & Fidler, 2003). This Down syndrome advantage was also present when Seltzer, Krauss, and Tsunematsu (1993) compared parenting stress in mothers of 35-year-old adults with Down syndrome to stress in mothers of adults with other forms of mental retardation.

Although a few studies do not find advantages for families of children with Down syndrome versus with other disabilities (e.g., Cahill & Glidden, 1996; Hanson & Hanline, 1990), the large majority do. However, this advantage is not seen when comparisons are made to parents of children with same-age, typically developing children (Roach, Orsmond, & Barratt, 1999; Scott, Atkinson, Minton, & Bowman, 1997). Furthermore, many studies find that, apart from overall stress levels, parents report their children with Down syndrome as being especially reinforcing to them (Hodapp, Ly, Fidler, & Ricci, 2001). Although by no means problem free, parents and families of children with Down syndrome do seem to be advantaged compared to families of children with mental retardation overall.

What accounts for this potential Down syndrome advantage? Two explanations seem possible. First, parents and families may benefit from aspects of Down syndrome that are apart from the child's behavior per se. Down syndrome is a relatively common disorder known to laypeople and professionals alike and has many active parent groups. Parents are also more likely to be older and to have parented other children. Such factors might be considered variables that are associated with the syndrome itself. Second, on average, children with Down syndrome may differ from others with mental retardation. As we noted earlier, children with Down syndrome are generally considered to have upbeat personalities, sociable natures, and a relative lack of psychopathology. Although associated and child-related explanations are both possible—and the two are not mutually exclusive—the behaviors of children with Down syndrome probably at least partially account for parent and family reactions.

In thinking about this issue, we are also struck by the ways behaviors of children with different genetic syndromes might serve as stand-ins or proxies for certain behaviors (Hodapp, 2004b). These behaviors then elicit reactions from others. To take some examples, children with Down syndrome might be considered to have upbeat, sociable personalities and a relative lack of psychopathology; those with Prader-Willi syndrome show hyperphagia, obsessions and compulsions, and temper tantrums (Dykens,

1999); those with Williams syndrome seem friendly, even overly friendly, and anxious (Dykens, 2003). Similarly, many genetic syndromes show patterns of cognitive-linguistic strengths and weaknesses, which—as in the Williams syndrome versus Prader-Willi syndrome jigsaw-puzzle study—may elicit differential emotional and behavioral reactions from others. The task now is to identify which etiology-related behaviors, in which contexts, and for which people (parents, siblings, teachers), elicit which specific reactions from others.

Mix of Studies

Given the earlier, dominant view that parents and families coped poorly and that child characteristics were unimportant, most early family research adopted a group-difference perspective. Thus, most researchers of the 1960s and 1970s compared parents of children with disabilities to parents of same-age children without disabilities. In many ways, within-group variability became an “error” that detracted from finding group differences showing how poorly these families were actually coping.

Although there continues to be a need to document whether families of children with disabilities cope the same as, better, or worse than families of same-age typically developing children, these between-group studies are now being supplemented with many within-group studies (Hodapp, 2002). Such within-group studies are consistent with the change to a stress-and-coping perspective. If parents and families differ widely in how they cope, which factors might predispose certain parents to cope well and others poorly? The identification of such factors—in children, parents, and families as a whole—has now become a major focus of disability family research. Such within-group work also has both scientific and practical consequences. By identifying protective or risk variables in children, parents, and families, family researchers begin to understand the mechanisms by which better or worse adaptation comes about. We can now go beyond judgments of better or worse to understand why, exactly, some families cope well and others poorly.

Identifying mechanisms, in turn, allows us to know with whom, when, and how to intervene. If, for example, mothers who approach problems in a less active way are most at risk, interventions can be tailored to help these particular women. Parents or families also may be more adversely affected at certain times. In Down syndrome, for example, many hospitalizations, mostly for heart and respiratory problems, occur during the preschool years. For families of these children, but maybe not for other families, the preschool period may prove especially stressful. Finally, if we can understand which parents, siblings, and families are

most at risk, when they most likely face such risks, and the reasons such risks occur we may be able to better devise the contents and approaches of intervention. Linking stress-and-coping models with etiology-related approaches makes possible the eventual answers to these questions.

REMAINING ISSUES

Although developmentally oriented work has progressed greatly over the past 10 to 15 years, much remains to be done. Indeed, some of the field's basic issues remain unresolved. In an effort to facilitate developmentally oriented work in future years, then, we end this chapter by discussing five issues that are essential to continued progress.

Control-Contrast Groups

The control-contrast group issue continues to be problematic in studies of children with mental retardation and their families. Historically, this question revolved around the use of chronological age versus mental age comparison groups and was also tied to the issue of whether children with mental retardation develop differently from or slower than typically developing children. But as these issues have become more complicated in recent times, we first describe historical issues, then more recent concerns. Particularly when dealing with more recent concerns, we detail the many ways that control and contrast groups have been used in research examining children with different genetic syndromes of mental retardation.

Historical Background

Over the past 40 years, a long-standing controversy has related to two types of comparisons to typically developing children. One group, referred to by the term "defect theorists," asserted that etiology does not matter, that all children with mental retardation suffer from organic defects. These researchers generally compared children with mental retardation to typically developing children of the same chronological age.

An entire research tradition has shown that, relative to typically developing children, numerous aspects of cognition and language are deficient in children with mental retardation. Different researchers emphasized different core defects, including cognitive rigidity (Kounin, 1941; Lewin, 1936), memory processes (Ellis, 1963), discrimination learning (Zeaman & House, 1963), and attention-retention capabilities (Fisher & Zeaman, 1973; for a review, see Burack, 1990).

In all of these studies, children with mental retardation were matched to children of the same chronological age. But, as developmentalists repeatedly noted, mental retardation is, by definition, marked by slower rates of development (Burack, Evans, Klaiman, & Iarocci, 2001). On almost every measure, then, children with mental retardation will show lower levels of cognitive functioning than CA-matched typically developing children. As Cicchetti and Pogge-Hesse (1982) noted, children with mental retardation function below children of the same chronological age in most areas of cognition, but "*the important and challenging research questions concern the developmental processes*" (p. 279; italics in original). Such processes can only be determined using MA-matched typically developing controls, thereby showing which areas are more or less affected.

To give one example, Iarocci and Burack (1998) reevaluated the literature on attention deficits among persons with mental retardation. They concluded that attention deficits were much more likely to be found when matching between the groups of participants with and without mental retardation was based on CA rather than MA. Furthermore, even the few examples of deficits in studies with MA matching were not particularly strong methodologically, as confounding factors of organic etiology and institutionalization were not considered (Burack et al., 2001).

As we note in our discussions about control-contrast groups in etiology-based studies, the techniques for matching by developmental level continue to be discussed and developed (Mervis & Robinson, 1999; Sigman & Ruskin, 1999). Among others, Loveland and Kelley (1986) and Burack, Iarocci, Flanagan, and Bowler (2004) highlight the need to further fine-tune matching developmental level so that the matching is not by general developmental level but is linked to the specific task.

For certain issues, it may even be possible to forgo matching altogether. For example, Jarrold and Brock (2004), after criticizing most matching strategies because of unclear relationships between background matching measures and performance on the experimental task, advocate regression techniques. These techniques seem particularly useful for charting developmental change. Like all sophisticated statistical analyses, however, such techniques require sufficient numbers of participants and time points in order that change over time can be charted most effectively.

Contrast Groups in Etiology-Based Research on Children

As etiology-based developmental research has proliferated over the past decade, researchers have needed to choose ap-

TABLE 6.2 Strengths and Weaknesses of Some Common Etiology-Based Research Approaches

Control Group	Characteristics	Strengths-Weaknesses
<i>Strategies to Determine Whether a Specific Disorder Has Strengths-Weaknesses</i>		
1. None	Performance “against self”	Shows etiology strength.
2. Typical	Equated on MA Equated on CA	Shows relative strength (versus MA) or intact functioning (versus CA); unclear if profile is unique, partially shared, or similar to all persons with mental retardation (MR).
<i>Strategies to Determine Whether Behavioral Characteristics Differ from Others with Intellectual Disabilities</i>		
3. Mixed ID	Mixed causes of MR	Shows that etiology strength-weakness is not due to MR. Weaknesses = hard to find; control group changes across studies; mixed ≠ nonspecific.
4. Down	DS	Shows behavior not due to any syndrome, but DS has its own behavioral syndrome characteristics (may lead to inaccurate conclusions if DS = “all MR”).
<i>Strategies to Further Delineate Etiology-Specific Behaviors</i>		
5. Same-but-different MR	Etiology similar in behavior to group	Highlights fine-grained differences in behavior if two or more etiologies have similar behaviors to make contrast meaningful.
6. Special	Group with special behavior	Shows ways that etiology is similar to or different from group with special problem or profile (but without MR).

Adapted from “Strengthening Behavioral Research on Genetic Mental Retardation Disorders,” by R. M. Hodapp and E. M. Dykens, 2001, *American Journal on Mental Retardation*, 106, pp. 4–15.

appropriate control-contrast groups (some might prefer the term “comparison group” to “control group,” as no experimental manipulation is being performed; Burack et al., 2004). In Table 6.2, we present three broad research questions (comprising six research strategies) that have been commonly used in etiology-based behavioral research (from Hodapp & Dykens, 2001).

Do Children Show an Etiology-Related Profile?

Given the interest in relative strengths and weaknesses in different etiological groups, a first strategy is to have *no control or contrast group*. To determine whether children with Williams syndrome show strengths in language versus visuospatial processing, Bellugi et al. (1999) compared each child’s functioning on a language domain to that same child’s performance on another domain. Children thus become their own controls, as their functioning levels in one domain are compared to more general, overall functioning levels.

Although widely used, this self-as-control technique has several limitations. Technically, one can compare the person’s performance only on one versus another domain on the same test. Different tests are standardized on different samples, and intelligence test scores tend to increase from decade to decade (Flynn, 1999). One should therefore compare different domains only of the same test. In addition, such domains as theory of mind, mother-child interaction, and family functioning have few well-normed, reliable, or valid psychometric instruments.

A second technique also attempts to answer the relative strength or weakness question. Here, the researcher compares persons with mental retardation to *typically developing children of the same mental age*. Depending on the question of interest, the process might be thought of as comparing the child with mental retardation to typical children of similar functioning levels (Burack et al., 2004). To determine areas of adaptive strength or weakness, one might compare children with Down syndrome to typically developing children using the Vineland Adaptive Behavior Scales; to determine whether aspects of language are relative strengths, one might match on the child’s MLU to examine aspects of pragmatics or semantics. In each case, the researcher compares children with a particular genetic syndrome to typically developing children of similar age-equivalent performance.

But, at times, CA-matches may be informative. Specifically, only by comparing to typically developing children of similar chronological age can one determine if certain groups are “spared” in their functioning in a behavioral domain. A good example involves Williams syndrome, earlier thought to be spared in certain areas of language. Although sparing now seems unlikely for groups (as opposed to for a few individuals) with Williams syndrome (Karmiloff-Smith, 1997; Mervis et al., 1999), the test for spared functioning involves comparing to typically developing age-mates either explicitly (using a typical CA-matched group) or implicitly (using standard scores from a standardization sample). Researchers do need to be aware, however, that similar functioning

between CA-matched groups has not occurred due to the use of tasks that are not sufficiently sensitive or developmentally appropriate to detect group differences (Burack, 1997; Burack et al., 2001).

Are Such Profiles Seen in Children with Mental Retardation More Generally? This second general research question also features two often used techniques. In the first, researchers compare persons with a particular mental retardation syndrome to a *mixed or nonspecific group* who are equated on both mental age and chronological age. If behavioral phenotypes do indeed involve “the heightened probability or likelihood that people with a given syndrome will exhibit certain behavioral and developmental sequelae relative to those without the syndrome” (Dykens, 1995, p. 523), such a mixed or heterogeneous group best approximates those without the syndrome.

As before, several issues arise. The first concerns the proper mixture of the mixed group, and how to ensure that one’s sample does indeed approximate the larger population with mental retardation. Unfortunately, in contrast to our knowledge about many psychiatric disorders, the field of mental retardation has performed few such epidemiological studies. An additional issue concerns heterogeneity. Because children in this group possess a wide variety of conditions (and no clear conditions at all), this group may, in theory, be more heterogeneous in its functioning than groups from a single etiological group. Still, this heterogeneous group does constitute the best approximation to those without the genetic disorder of interest. Different researchers disagree as to the appropriateness of using or not using a mixed or heterogeneous group with mental retardation as the contrast group in studies of etiology-related functioning (for alternative viewpoints, see Burack, 1997; Hodapp & Dykens, 2001).

A second technique in this class compares one etiological group with *children with Down syndrome*. Although groups with Down syndrome are often used as a control group with mental retardation, we consider this strategy to be inappropriate. As a group, persons with Down syndrome show relative weaknesses in various aspects in language, and they may have particular personalities and a general lack of psychopathology. Especially when examining etiology-related profiles in these areas, then, comparing a group with the etiology of interest to children with Down syndrome as the control group seems ill advised.

Still, there may be certain instances in which children with Down syndrome constitute an informative contrast group. Consider, for example, the issue of modularity and the finding that auditory short-term memory levels are generally tied to levels of grammar in children with

Williams syndrome (Mervis et al., 1999). If indeed children with Down syndrome also show such cross-domain connections, more evidence has been amassed for a universal connection across these two domains (i.e., the same connection has occurred in two separate syndromes). Thus, although the use of children with Down syndrome as a stand-in for all children with mental retardation, though widely done, seems ill advised, there may be occasions in which children with Down syndrome may constitute an informative contrast group.

How Do Children in a Specific Etiological Group Compare to Nonretarded Persons with Similar Conditions or Behaviors? This final approach compares persons who have a genetic syndrome to “specialized” nonretarded persons in an area of interest. Here again, the general approach can be seen through the use of two specific research techniques. In the first, persons with a particular syndrome are compared to *nonretarded persons with a diagnosed psychiatric disorder*. Dykens, Leckman, and Cassidy (1996) compared persons with Prader-Willi syndrome to nonretarded outpatients with Obsessive-Compulsive Disorder. With very few exceptions, the two groups were very similar in their mean number and severity of compulsions and in percentages within each group displaying most behaviors (e.g., cleaning, ordering/arranging, repeating rituals).

A specialized-group strategy can also be shown in a second technique, this one comparing to *nonretarded persons who show particular cognitive-linguistic profiles*. How, for example, might children with Prader-Willi syndrome, who show simultaneous-over-sequential processing abilities, compare to nonretarded persons who similarly show such simultaneous processing advantages? How do children with Prader-Willi syndrome compare to typically developing children who are “good puzzlers”? Are the two groups approaching problems in the same way? This strategy probably best approaches Cicchetti and Pogge-Hesse’s (1982) call for research that examines developmental processes in children with mental retardation. Although using specialized nonretarded groups risks producing no-difference findings, we still consider this approach informative and, at present, underutilized.

Contrast Groups in Research on Mother-Child Interaction and Families

The issue of control-contrast groups becomes even more complicated when one thinks about parent-child interactions and families. In the field of mother-child interactions, early studies examined parental (mainly maternal)

behaviors to children of the same chronological age as typically developing children. Beginning with Rondal (1977), groups came to be equated more on age-equivalent scores, and either mental-age or language-age comparisons have predominated over the past few decades.

As we gain in our knowledge of children with different types of mental retardation, such issues become more complicated. Consider the finding that children with Williams syndrome show relative strengths in language (compared to mental age), or that children with Prader-Willi syndrome show excellent performance, even above typical children of identical chronological age, on jigsaw puzzles (Dykens, 2002). What is the appropriate maternal input relative to these tasks?

One suggestion is that children with different genetic mental retardation syndromes might be used as proxies for particular emotional-behavioral problems, personalities, or skill levels on specific tasks (Hodapp, 2004b). In such analyses, one might use children with Prader-Willi syndrome versus with Williams syndrome as good versus poor jigsaw puzzlers, respectively. Other syndromes might also be used as proxies for one or another etiology-related behavior. The question then becomes whether parents or others react similarly or differently to nonretarded children who have similar high or low skills on a specific task. Throughout these parent-child interactions, however, some variant of MA or level-of-functioning comparisons seems best.

But different issues arise when discussing control-contrast groups involving families. In fact, most studies compare families of children with mental retardation to families of typically developing children of the same chronological, not mental, age. The reasoning here involves family life cycles (Carter & McGoldrick, 1988). Consider the case of a child who is 13 years old but functioning at the 5-year level (i.e., MA = 5 years). Which aspect of the child—the child's chronological age or mental age—is most salient to families? Under family life span theory, having lived for 13 years with a child with mental retardation may be the most important issue for parental stress levels and family coping styles.

We are left, then, in a strange place. For most issues of the child's own development, MA comparisons, or comparisons related to some other level-of-functioning measure, seem preferable most of the time. The few exceptions concern instances of possibly spared development, when it will be useful to add comparisons to same-age, typically developing children. Similarly, MA or other level-of-functioning comparisons seem best when one is examining maternal behaviors in mother-child interactions. In contrast, due to issues involving family life cycles, CA comparisons might

be best when considering families of children with mental retardation.

Within-Group Heterogeneity

Some of the most exciting phenotypic studies currently examine individuals with the same etiology, but who differ in one or more aspects of behavior. Although the reasons for within-group heterogeneity are not always known, a few factors are beginning to be examined.

Within-Syndrome Genetic Variants

The first factor involves slight genetic variations within a particular genetic syndrome (for a review, see Einfeld, 2004). To give a few examples, in Prader-Willi syndrome, a distinction exists between individuals who have a deletion on chromosome 15 contributed from the father (i.e., paternal deletion) versus those who have two chromosome 15s from the mother (i.e., uniparental maternal disomy, or UPD). Individuals with UPD more often suffer from psychotic disorders that first appear in early adulthood (Clarke et al., 1998; Vogels et al., 2004). But behavior in Prader-Willi syndrome may also be differentially affected by the child's type of deletion. M. G. Butler et al. (2004) noted that deleted individuals have one of two distinct types of deletions. In Type I deletion, individuals have a larger deletion than in Type II deletions. Individuals with Type I deletions show lower adaptive behavior scores and several specific obsessive-compulsive behaviors. Although preliminary, such within-syndrome genetic differences seem an important avenue of research in coming years.

Non-Etiology-Related Background Genetics

A genetic disorder—be it a trisomy 21 (Down syndrome) or a deletion on chromosome 15 (Prader-Willi syndrome)—affects only a single chromosome or part of a chromosome. All other chromosomes are left unaffected. Background genetics involves the idea that, in addition to one's genetic disorder, these other chromosomes contain genetic predispositions that are at work in every individual.

In studies from several different laboratories, researchers are using background genetics to examine proneness to different behaviors and treatments. For example, May, Potts, Phillips, Blakely, and Kennedy (2005) examined the effects of two different genetic variants, which had earlier been shown to predispose nonretarded individuals to increased aggression. Their findings suggest that, in persons with mental retardation as well, those who have one versus another genetic variant also have aggression-related effects. Similarly, Roof, Shelton, Wilkinson, Kim, and Dykens (2005) examined genes

involved in psychotropic drug metabolism in individuals with Prader-Willi syndrome. In both cases, researchers are going from genetic, clinical-genetic, or pharmacogenetic findings earlier shown to operate in typical, nonretarded persons and applying these findings to persons with mental retardation. Such studies highlight the idea that individuals with genetic disorders are more than their genetic disorders per se.

Developmental Change and Its Effects

In discussing sequences and cross-domain relations, we noted that, in many syndromes, strengths become stronger and weaknesses weaker as children get older. In the Jarrold et al. (2001) study, for example, adolescents and young adults with Williams syndrome advanced at faster rates in measures of linguistic versus visuospatial processing. Why such findings occur remains mostly unresolved. Although sheer amount of experience in different types of task is one possibility (Rosner et al., 2004), no studies have yet looked in depth at the interplay between the environment and the child's development at various age spans.

An additional issue involves concomitant brain changes. So far, only a few studies have even tied etiology-related cognitive-linguistic profiles to brain-related tasks. For example, following from hypotheses developed by Nadel (1996, 1999) about hippocampal deficits in children with Down syndrome, Pennington, Moon, Edgin, Stedron, and Nadel (2003) compared these children to MA-matched typically developing children on two sets of tasks. The first set related to functioning of the prefrontal cortex, which involves holding information in active or working memory. The second set examined hippocampal functioning, which relates to the storage of episodic information into long-term memory. As predicted, children with Down syndrome performed more poorly than MA matches on tasks involving the hippocampus and equivalently on tasks relating to the prefrontal cortex.

Although the Pennington et al. (2003) study is noteworthy as one of the first brain-related examinations of children with any specific etiology, other, related questions remain unanswered for children with all genetic etiologies. How, for example, does using "strong skills" over time (and not using one's "weak skills") change brain circuitry? Do compensations occur, and how well can children who compensate perform a host of different types of tasks? In no genetic disorders have researchers yet tied together—over time—experience, behavior, and brain functioning.

Need for Greater Amount of Basic Information

Compared to our knowledge about most other diagnostic categories covered in the *Diagnostic and Statistical Manual*

of Mental Disorders and the *International Classification of Diseases*, our knowledge about mental retardation remains woefully lacking. We do not know, for example, how many persons with mental retardation there are, or what percentages have Down syndrome or any other genetic (or other) condition. Granted, some issues are difficult due to basic disagreements about definition of the group itself. Recall our earlier discussion about changing mental retardation IQ cutoffs, which by definition affect prevalence rates.

But beyond definition and prevalence, we continue to lack basic information about a wide range of issues. For example, we know little about the health status of children with many different disorders, even those in whom health-related problems seem reasonably common. Consider the health issues in Down syndrome, in which heart problems and surgeries to repair such problems often occur in the 1st year of life. How often do such hospitalizations and surgeries occur? How might these and other health issues affect these children's development or their family's functioning? Although some larger-scale, epidemiological studies of health-related issues are beginning to appear on certain syndromes (e.g., J. V. Butler et al.'s, 2002, work on Prader-Willi syndrome), the mental retardation field remains only vaguely knowledgeable about health-related issues in many different groups.

Other topics are also generally unresearched. Consider the entire issue of gender differences. Although a common issue in developmental psychology proper and a major factor in clinical depression and dysthymia, the topic remains almost completely unstudied in groups with mental retardation. Hodapp and Dykens (2005) recently surveyed the reporting of gender and analysis of gender differences in the *American Journal on Mental Retardation* and the *Journal of Intellectual Disability Research*, the two main journals of mental retardation behavioral research. They found that, in these two journals, only about a quarter of research articles both listed the number of participants of each sex and analyzed for sex differences. Given the inattention to such basic child characteristics, we remain unsure of how gender identity develops. Similarly, in typically developing samples, girls and women seem about twice as likely as boys and men to become clinically depressed sometime during their lives (Wolk & Weissman, 1995), and sex differences in prevalence rates of female (as opposed to male) depressive symptoms (not associated with full-blown depression) begin in the 10- to 15-year period (Garber, Keiley, & Martin, 2002). We do not know whether rates of depression or depressive symptomatology also show strong gender changes when children have mental retardation (or different types of mental retardation).

Consider as well the entire issue of child abuse. For many years, child abuse professionals suspected that children with mental retardation were more likely to be abused (Westcott & Jones, 1999). But only in the past few years have such differential rates been documented in a strong, epidemiologically based study that joined records from schools, child protective services, criminal justice, and hospitals-clinics. Once such records were joined, Sullivan and Knutson (2000) were able to document that children with mental retardation are approximately 4 times more likely than nondisabled children to be abused. Now that we have the basic numbers, countless additional questions arise concerning when and what types of abuse occur, and why these children suffer abuse so often.

What Do Others React To?

In considering the high rates of child abuse of children with mental retardation, we return, from a slightly different angle, to the entire problem of what parents or others react to in the child with mental retardation. This simple-seeming problem actually has several subproblems buried within.

Do Others React to Behavior Alone?

Following Bell (1968) in a theoretical sense and Rondal (1977) in terms of input language, our original thinking focused on behavior. That is, in children with mental retardation or with particular syndromes, parents will react to the behavior that they experience from their children. Our initial ideas also focused on a single, salient behavior from children with one or another genetic mental retardation syndrome (Hodapp, 1999). More recently, we have come to question which of many etiology-related behaviors might matter, to whom, and under which circumstances (Hodapp & Ly, 2005).

But behavior may be one among several of the child's personal characteristics to which parents respond. Consider the babyface studies discussed earlier. In both cases, unfamiliar adults (Fidler & Hodapp, 1999) and mothers (Fidler, 2003) were responding to the more immature, "babylike" faces of children with Down syndrome. We have recently been intrigued by the impact of child hospitalization and health problems on parental and familial reactions. In short, we suspect that the child's behavior is not the sole personal characteristic to which parents and others respond.

Do Others' Reactions to Identical Behaviors Differ Based on the Child's Specific Syndrome?

In several studies, the child's etiological group may moderate parental reactions to the child's behavior (or other personal characteristic). Specifically, parents react to the

child's behavior, but mainly in the context of what parents know or perceive of their child's syndrome. In one study, for example, Ly and Hodapp (2002) asked parents of children with Down syndrome versus with other forms of mental retardation to make causal attributions in response to hypothetical vignettes in which their child performed each of two common, noncompliant behaviors. Parents of children considered more sociable and outgoing attributed their child's noncompliant behaviors to normative concerns ("My child is acting like other children his or her age"). But such connections between child personality and normalizing behaviors were found only in the Down syndrome group. Thus, among parents of children with Down syndrome, those who saw their child as more sociable also more highly rated normalizing as the reason for their child's noncompliance. But among parents of children with mixed forms of mental retardation, no such connections existed between child personality and parental ratings of normalizing attributions.

Such findings suggest a complex interplay between the child's behavior, on one hand, and parental knowledge or perceptions of etiology-related behavior, on the other. In the case of Down syndrome, the degree to which parents felt that their child possesses a "Down syndrome personality" elicited greater degrees of parental normalizing attributions. In contrast, no such connections between perceived child personality and parental normalizing attributions occurred for parents of children with mental retardation in general. There seems, then, to be a complex interaction between the behaviors themselves and what mothers know about their child's type of mental retardation.

What Do Parents Know?

If parental perceptions and knowledge of their child's etiology are so important, what do parents know? Although a major area in parenting studies of typically developing children (Goodnow, 2002; Okagaki & Divecha, 1993), parental perceptions and attributions are relatively unexplored among parents of children with disabilities (Ly & Kazemi, 2005). In a few syndromes, however, we do have some sense of what parents know about their child's etiology. For example, Fidler, Hodapp, and Dykens (2002) asked parents of children with Prader-Willi syndrome, Down syndrome, and Williams syndrome about several education-related aspects of their child's behavioral characteristics and school accommodations. Whereas parents of children with Down syndrome were aware of their child's cognitive-linguistic strengths (e.g., visual short-term memory) and weaknesses (e.g., expressive language), parents in the two other groups knew much less. Parents of children with Prader-Willi syndrome knew of their child's extreme overeating and tantrums, but were less aware of

their child's strong visuospatial abilities. Similarly, parents of children with Williams syndrome were aware of their children's many fears and anxieties (Dykens, 2003), but less aware of these children's propensity to have relatively strong linguistic skills and weak visuospatial skills.

Though suggestive, these findings leave unanswered countless other questions. Where do mothers receive their information, and when do they receive it? How might such information be related to parental access to and abilities in searching the Internet, or to a parent's degree of involvement with an etiology-related parent group? How do schools and other service systems relate to parents who present etiology-based information, particularly given the general disregard of etiology-related information that has historically characterized the field of special education (see Hodapp & Fidler, 1999, for a review)? To these questions, we remain woefully uninformed.

CONCLUSIONS AND FUTURE DIRECTIONS

Fields, like children, develop at different rates at different times. As we have shown, work on both organismic and contextual developmental issues has increased rapidly over the past decade. Many of the most exciting studies involved children with genetic mental retardation syndromes or the etiology-related reactions to these children by parents, siblings, and others. Considered overall, the past 10 to 15 years have constituted an exciting, even exhilarating, time for developmental studies of children with mental retardation and their families.

And yet, for all of the information learned during the past decade, we remain uninformed about many issues. Many of these unknown areas relate to questions of control-contrast groups, within-syndrome heterogeneity, developmental change, basic health information, and child-parent and child-family relations. But moving beyond these specific content areas, we also see two major needs for the future.

Need for Between-Level Syntheses

The first, more scientific need concerns examining how different levels of analyses relate to one another. Like all systems theorists, developmentalists conceptualize the child in relation to within-child systems (e.g., brain) and such out-of-child systems as the family (Sameroff, 1995). The question of how development occurs can therefore be asked on multiple levels simultaneously, and changes in one level often relate to changes at other levels.

For mental retardation, one can look in both directions: within and outside of children themselves. How, for example, do changes in etiology-related strengths and weaknesses over time—in, for example, children with Williams syndrome or with Down syndrome—relate to changes in brain structures or function? How do children's behaviors affect others in their surrounding environments? Do changes in others' behaviors reflect back on children themselves?

Although currently unknown, such linkage issues seem especially timely given the history of the mental retardation field, particularly the rise of etiology-related studies over the past decade. As Hodapp (2004a) noted, research on behavioral phenotypes can be characterized as having its own Wernerian developmental pattern. Within this perspective, the years up to and through the 1980s could essentially be considered the prehistory of etiology-based studies, with little information and more global and undifferentiated senses of organicity and etiology. In contrast, the 1990s featured an explosion of information about children with many different disorders. For at least Fragile X, Prader-Willi, Williams, and a few other syndromes, researchers determined basic cognitive, linguistic, and adaptive profiles, as well as the nature and course of etiology-related maladaptive behaviors. For the most part, however, such bits of information were unconnected, leaving knowledge that is, in Werner's terms, "differentiated but unintegrated."

Now, as we enter the early years of the new century, we are ready to put together the various levels. We are poised to examine children's development itself, in terms of both sequences and cross-domain relations, as well as to examine how that development relates to levels within and without. The search for gene-brain-behavior connections, the use of various syndromes as models for biobehavioral syntheses, the connections of child behaviors to parental reactions and behaviors—all constitute the coming together of levels of the system.

Again, such multilevel approaches fit well within the larger field of developmental psychopathology. Indeed, in summarizing the history of advances in the field of developmental psychopathology, Cicchetti and Dawson (2002, p. 418) noted:

Most of what is known about the causes, correlates, course, and consequences of psychopathology was gleaned from investigations that focused on relatively narrow domains of variables. Yet it is apparent from the questions addressed by developmental psychopathologists that progress toward process-level understanding of mental disorder will require research designs and strategies that call for the simultaneous

assessment of multiple domains of variables both within and outside of the developing person.

So, too, with our understanding of individuals with mental retardation. Whereas more narrowly tailored, single-discipline analyses have characterized most studies until now, more collaborative, multidisciplinary studies and findings will likely pave the way for tomorrow's advances.

Need for Greater Attention to Etiology-Based Interventions

An additional issue concerns intervention. Since Cicchetti's (1984) earliest writings, developmental psychopathology has been a hybrid field, one in which proponents are simultaneously interested in both basic and applied issues. To some researchers, Williams syndrome is a genetic etiology that tells us much about whether (or not) humans show linguistic modularity; to others, the syndrome is one showing particularly high rates of anxiety and fears that may require clinical interventions (Dykens, 2003). Both are true; both simply reflect different sides of the single coin of developmental psychopathology.

Given these interests in using basic information to help us develop more precise, targeted interventions, we again see the importance of etiology-based research. Once one knows that children with Williams syndrome, in general, show relatively strong linguistic and weak visuospatial skills, one can begin to consider tailoring intervention programs. Once one knows about the relative strengths seen in most children with each of several genetic disorders, one can begin to know how to intervene.

The task now is to take our knowledge of etiology-related profiles and determine if intervention strategies can either play to strengths or ameliorate weaknesses. From one direction, for several etiological groups we may currently have enough preliminary information to directly test hypothesized underlying functional deficits. If language is strong and visuospatial abilities weak in Williams syndrome, or if visual-spatial (particularly jigsaw puzzle) abilities are strong in Prader-Willi syndrome, we may be ready to develop new and more effective ways to intervene.

From the opposite perspective, several subdomains of functioning now have sufficient normative information that etiology-related abilities can be directly examined for a complex behavior's component skills. Consider reading. For many years, Buckley and her colleagues (Buckley & Bird, 2002; Byrne, Buckley, MacDonald, & Bird, 1995) argued that children with Down syndrome should be taught to read. Given these children's relative strengths (i.e., above overall MA levels) in visual short-term memory and

weaknesses in grammar, expressive language, and articulation, reading might even be considered an entryway into language for these children.

Although such arguments may seem reasonable, only recently have researchers directly examined children with Down syndrome using fine-grained reading tests. In three studies, Snowling, Hulme, and Mercer (2002) compared typical children to children with Down syndrome on segmentation, nursery rhyme knowledge, rhyme detection, and phoneme detection. They also examined letter names and sounds, print in the daily environment, single-word reading, and nonword reading. As might be expected, children with Down syndrome with good, as opposed to poor, phonological skills were better readers, but letter-sound knowledge was not a concurrent predictor of reading performance. Further, children with Down syndrome performed significantly worse than control children on rhyme judgment.

Compared to typical children, then, children with Down syndrome may follow a qualitatively different path as they develop reading and phonological skills. These children may be reading without the full understanding of all aspects of phonemic awareness. To some extent, children with Down syndrome use grapheme-phoneme strategies but are also accessing other strategies (such as whole-word recognition). Such detailed knowledge about etiology-related profiles could only be attained through more detailed, fine-grained tasks that tap specific subskills involved in reading. The task now is to use that information to develop more effective reading instructions for these (and other) children.

We end this chapter with many more questions than answers, with a bucketful of important, unanswered questions that remain to be tackled. At the same time as we are humbled by just how much information remains to be discovered, we are also heartened by the progress that has already been made. Indeed, comparing developmentally oriented knowledge in mental retardation to only 10 or 15 years ago, progress is staggering. Like a child's development, our trajectory is clearly upward, rapidly so over the past decade. Our hope—and expectation—is that upcoming decades will continue to feature the same, seemingly exponential advances in our understanding of children with mental retardation and their families.

A major principle of developmental psychopathology pertains to the reciprocal interplay between normality and pathology. At this juncture, adaptive and maladaptive processes encounter a multiple-levels-of-analysis perspective from molecular to sociocultural systems (Cicchetti & Dawson, 2002). Research in the field of developmental language disorders has a long history, being intimately intertwined with the exploration of normal language acquisition. Accounts describing normative language development are often mutually exclusive and still a matter of intense debate. Even after many years of study, the fundamental mechanisms and neural substrate that mediate language acquisition are not fully delineated. Thus, typical and atypical language trajectories as well as their interface characterize an enduring research interest and illustrate the strength of a developmental psychopathology approach (Cicchetti & Toth, 1992).

Work was supported by grants from NICHD (RO1-HD29419) to AAB and the German Research Council to SH (HE3500/1), a Rutgers University Board of Trustees Excellence in Research Award to AAB, with additional support from the Elizabeth H. Solomon Center for Neurodevelopmental Research. We thank Dr. Andreas Keil for helpful comments on this chapter.

Disorders of language rank among the most prevalent of developmental disabilities. It is estimated that roughly 20% of preschool- and school-age children suffer from deficits in oral and/or written language (Beitchman, Nair, Clegg, Patel, et al., 1986; S. E. Shaywitz & Shaywitz, 2001). Disturbances in language development may be associated with sensory impairments (e.g., hearing loss, blindness) or neurological disease (e.g., acquired aphasia, epilepsy). They may be part of several syndromes related to mental retardation, such as Down syndrome or Fetal Alcohol syndrome. Language problems may also accompany pervasive developmental disorders, such as Rett's syndrome or Autism Spectrum Disorders. Anomalies in language skills characterize one crucial aspect of the autistic triad (impairments in communication, social interaction, and behavior repertoire) and represent an important feature of the syndrome as a whole.

A subset of children demonstrate significant limitations in oral language ability despite absence of the aforementioned causes, a condition often termed *specific language impairment*. More than 50% of children having specific language impairment continue on to develop dyslexia, encompassing difficulties in the literacy domain (e.g., Stark et al., 1984; Tomblin, Zhang, Buckwalter, & Catts, 2000). Conversely, many dyslexic individuals show deficits in

parameters of oral language (e.g., Byrne, 1981; Joanisse, Manis, Keating, & Seidenberg, 2000). Longitudinal studies as well as family genetic studies demonstrate considerable overlap in etiology and co-occurrence between specific oral language disorders and reading problems, such as dyslexia (Catts, 1993; Flax et al., 2003; Rissman, Curtiss, & Tallal, 1990; see L. B. Leonard, 1998; Snow, Burns, & Griffin, 1998). To highlight the continuity between language and reading/spelling difficulties, Tallal coined the term *language learning impairment* (Tallal, Allard, Miller, & Curtiss, 1997). Epidemiological research also indicates that language-learning impaired individuals are vulnerable to psychosocial problems as well as deficits in regulation of affect and behavior (e.g., Beitchman et al., 2001; Benasich, Curtiss, & Tallal, 1993; Gadeyne, Ghesquière, & Onghena, 2004).

This chapter focuses on specific language impairment and developmental dyslexia from a converging methodological/developmental perspective under the rhetoric of language learning impairment. We propose a multilevel approach, which aims to integrate molecular, cellular, macroscopic, and behavioral evidence. Current etiological models from psychological and biological domains are addressed. Prospective studies beginning early in the life span and studies targeting remedial intervention complete the picture. The chapter concludes with recommendations and future directions regarding basic research as well as remedial work in developmental language disorders.

A HISTORICAL PERSPECTIVE ON DEVELOPMENTAL LANGUAGE DISORDERS

The study of individuals with developmental language disorders dates back to the nineteenth century. It was in 1822 when Franz Joseph Gall, the originator of what was later termed *phrenology*, published descriptions of children who had remarkable difficulties in oral language but did not show characteristics of other known syndromes. More than 50 years later, the first cases with unexpected disturbances in literacy skills were reported and considered a member of the family of aphasia. The early publications on language deficits entailed a series of case studies that continued to the 1st decades of the twentieth century. The incipient reports were written mainly from a medical perspective and not seen as pertinent for educational purposes; subsequent work accentuated the need for implementing therapies. Up to the 1990s, several different diagnostic classifications were suggested to describe these language disabilities of

unknown origin. In what follows, we provide a brief historical survey of the study of specific language impairment and developmental dyslexia.

Research on Language Learning Impairments: The Origins

Research on language-based learning impairments has its roots in the study of language disturbances that typically result from a single lesion to the left cerebral hemisphere. These medical conditions are known as the aphasia. As early as 1822, French-German anatomist and physiologist Gall described a patient who could not voluntarily repeat spoken words. Gall linked this impairment to trauma of the left brain. However, it was not until the seminal studies of neurologists Pierre Paul Broca (1861) and Carl Wernicke (1874) that localization of language functions received particular interest. In his native France, Broca reported a case of speech loss due to a lesion in the posterior part of the second and third frontal convolution. This left hemisphere area was then designated “Broca’s area.” In Germany, Wernicke discovered that damage to the first temporal gyrus on the left might induce deficits in language comprehension and literacy skills. This particular region has become known as “Wernicke’s area.”

In 1872, Sir William Henry Broadbent, a physician from Yorkshire, reported cases of “loss of speech and writing.” The medical history of an intelligent adult male who suffered from right hemiplegia reads as follows:

It was impossible to understand him when he attempted a phrase, or when he tried to say anything to which I had no clue. He laboured through the title page of a book given him to read, but, without looking at the book, only one or two words would have been recognised. A peculiarity of his attempts to read or speak was his persevering effort to master a word, syllable by syllable, by trying on and on again. (pp. 161–162)

Inspired by the *Zeitgeist*, the German physician Adolf Kussmaul became involved in the study of acquired language disorders and introduced the concepts of “word deafness” and “word blindness.” His terminology reflected the observation that reading problems could occur as an isolated condition:

In medical literature we find cases recorded as aphasia which should not properly be designated by this name, since the patients were still able to express their thoughts by speech and writing. They had not lost the power either of speaking or of writing; they were no longer able, however, although the hearing was perfect, to understand the words which they heard,

or, although the sight was perfect, to read the written words which they saw. This morbid inability we will style, in order to have the shortest possible names at our disposition, word-deafness and word-blindness [*surditas et caecitas verbalis*]. (Kusssmaul, 1877, p. 770, cited in Hallahan & Mercer, 2002)

A Brief History of Specific Language Impairment

The literature of the late nineteenth century provides several case histories of children showing impairments in expressive language. English and French authors usually published their brief descriptions under the umbrella of “congenital aphasia” or “aphasie congénitale,” a phrase coined by deaf instructor Léon Vaïsse in 1866. Broadbent (1872) presented a then detailed report on an 11-year-old boy, including observations on general intelligence, speech, and literacy. Typical remarks were:

He plays with other children. . . . He can find his way about the streets. . . . Can be sent errands with a note, . . . will see that he has the proper change if told beforehand how much it should be. . . . He clearly understands everything that is said to him, but cannot utter a single connected sentence, and has never talked. To most questions he answers by a sound which may be represented by “keegurkruger,” whether the required answer be long or short. He says “no” distinctly, “yes” indistinctly, that is, without the y or s; helping out the meaning by an affirmative nod. . . . He wrote his name pretty well, and copied several words from a printed card in written characters, but could not write yes or no when told to do so; could not write the name of the street in which he lived. Did not understand on this or any occasion the simplest *written* request. (pp. 156–157)

The German literature of the late nineteenth century used the designation *Hörstummheit* (hearing mutism or audimutism) to describe children suffering from congenital aphasia. This term was introduced in 1886 by one of the Sprachärzte (literally, “speech doctors”), Raphael Coën, who resided in Austrian Vienna. The speech doctors devoted their work to the diagnosis and treatment of communication disorders. Based on clinical observations, they presented extensive reports of children with severe limitations in language output, proposed etiological models, and designed therapy programs for the condition under consideration (see Weiner, 1986, for a stimulating review).

In 1886, citing Kusssmaul’s transcoding diagram of speech processing, Coën inferred that the impediment must be functional in nature. Accordingly, the brain of the affected child was thought to be equipped with a normally

functioning “sensory center for acoustic word images (sound images).” The pathway between this center and the “center for conceptions” (“ideational center”) was believed to be intact. Hence, the audimute child should be capable of perceiving, storing, and understanding spoken words. However, in this view, he or she either could not utilize the connection between the sound image center and the “motor center for the coordination of the sound movements into spoken words,” or the motor center for speech itself was only partially operative. Consequently, the child was thought to be mute or near mute, a condition resembling that of Broca aphasia.

Coën suggested that the functional disturbance was hereditary, but might also be related to psychological factors and trauma. Guided by his theoretical assumptions as well as observations on normal child development, he devised a therapy that encompassed both intensive “bodily gymnastic” and “mental gymnastic” (1886, 1888) methods. The former building block included exercises for general functioning. The mental gymnastic component aimed at (1) assembling visual images, word sounds, and semantics in the sensory and ideational centers; (2) training of sensorimotor pathways and the motor coordination center by using written sound symbols; and (3) implementing elementary instructions in reading, writing, and arithmetic. Adding to these building blocks, three speech doctors from Berlin, Leopold Treitel (1893), Hermann Gutzmann (1896), and Albert Liebmann (1898), highlighted the importance of attention and memory as mediating factors in therapy.

Liebmann’s exceptional commitment to the education of practicing physicians motivated him to offer a refinement of the syndrome. In the style of acquired aphasia terminology, he proposed three subtypes of hearing mutism (1898): One, the motor type, concerned children who were near or actually mute, or else uttered only unintelligible sounds due to a malformation of the speech organs. A second form, the sensorimotor, was said to involve children who succeeded only in comprehending single words. The third or sensory type was characterized by a lack of language comprehension. In the literature in English of the early twentieth century, reports on the last subtype were published under the notion of “congenital word deafness” (McCall, 1911) or “congenital auditory imperception” (Worster-Drought & Allen, 1929).

Whereas early research on developmental language disorders focused on cases with profound limitations in expressive language, subsequent studies also included children whose abilities extended to multiword utterances. This led

to a growing interest in grammatical and syntactic structures of disturbed language (e.g., Menyuk, 1964; Morley, Court, Miller, & Garside, 1955). As the twentieth century progressed, systematic use was made of intelligence measures, such as the Binet and Simon test. Despite this progress in methodology, validity of the studies was limited in a variety of ways: Often, sample size did not exceed two cases, an adequate control group was missing, language data were frequently based on an insufficient number of utterances, and information on experimental context was rarely given (L. B. Leonard, 1979).

Paralleling methodological and conceptual developments, terminology underwent several changes. In the 1950s, efforts in distinguishing deficits of production from those involving both comprehension and production resulted in the terms *expressive developmental aphasia* and *receptive-expressive developmental aphasia*. Stimulating contemporary theories and presaging a still ongoing debate (see section on Psychological Models), Benton (1964, p. 51) then suggested that the latter condition might be based on a “higher-level auditory perceptual deficit”:

This is, of course, not the same as saying that they are “partially” deaf. It is not so much a question of elevation of auditory thresholds (it is evident that many of these children show no such elevation) but of deficits in the orientational, discriminative and integrative aspects of auditory cognition.

The term *dysphasia* appeared in the 1960s and became the most frequent term in use (*developmental dysphasia*) about 2 decades later (classically, the prefix “a-” indicates absence, whereas “dys-” denotes difficulties). However, both terms did not prevail. Many other phrases were created to describe the syndrome, such as “deviant language” (L. B. Leonard, 1972), “delayed language” (Weiner, 1974), “developmental language disorder” (Aram & Nation, 1975), “specific language impairment” (Fey & Leonard, 1983), and “language/learning impairment” (Tallal, Ross, & Curtiss, 1989b). “Specific language impairment” has proved to be the most widely adopted notion in the current Anglo-American literature (L. B. Leonard, 1998). Because of the relationship between oral language disability and subsequent problems in literacy skills, several contemporary researchers also preferred the term *language learning impairment* (Tallal & Benasich, 2002). Its *raison d’être* also manifests in partially overlapping etiological theories proposed for developmental dyslexia (see the following paragraph).

A Brief History of Developmental Dyslexia

As early as 1887, German ophthalmologist Rudolf Berlin characterized a group of patients who experienced severe reading difficulties following cerebral disease. He classified them as having “dyslexia” but regarded the disorder as a manifestation of aphasia. Subsequently, Joseph Déjérine (1892), a Swiss-born neurologist, linked discrete reading disability (“pure word blindness”) to a disconnection of the left angular gyrus from the right visual cortex. It was only a couple of years later when English school physician Pringle Morgan (1896, p. 1378) published an article describing for the first time a “congenital” form of reading disorder:

Percy F. . . . aged 14 . . . has always been a bright and intelligent boy, quick at games, and in no way inferior to others of his age. His great difficulty has been—and is now—his inability to learn to read. This inability is so remarkable, and so pronounced, that I have no doubt it is due to some congenital defect. He has been at school or under tutors since he was 7 years old, and the greatest efforts have been made to teach him to read, but, in spite of this laborious and persistent training, he can only with difficulty spell out words of one syllable. . . . His visual memory for words is defective or absent; which is equivalent to saying that he is what Kussmaul has termed *word blind* (*caecitas syllabaris et verbalis*).

Morgan assumed that Percy’s disorder was caused by a defective development of the left angular gyrus, which is consistent with Déjérine’s tenet.

The term *congenital word blindness* was adopted and used by James Hinshelwood, a Scottish eye surgeon, in his classic 1917 monograph. His account of the rhetoric or synonym *congenital dyslexia* referred to

children with otherwise normal and undamaged brains characterised by a difficulty in learning to read so great that it is manifestly due to a pathological condition, and where the attempts to teach the child by the ordinary methods have completely failed. (p. 40)

Hinshelwood noted that the condition might be hereditary and that it was more common in males than it was in females. He postulated poor visual memory for words and letters as the primary disability. Because the symptoms paralleled those in adults with acquired reading deficits, he believed that the congenital form was caused by faulty development of the angular gyrus of the dominant hemisphere (see Morgan, 1896). Hinshelwood emphasized the need to observe a strict nomenclature to avoid confusion between children with the “pure type of congenital word-blindness”

and “generalized cerebral defects.” He was also convinced that the pure type is susceptible to remedial strategies based on multisensory training.

The earliest theoretical account incorporating biological, psychological, and behavioral information on developmental dyslexia was made by American neuropathologist Samuel Torrey Orton (1925, 1937). Orton observed a striking tendency in reading-disabled children to twist the order of letters in words while reading or spelling, which led him to introduce the term *strephosymbolia* (literally, twisted symbols). Because letter reversals were “not an outstanding feature” (1937, p. 93) of the condition, he also recommended the notion of “specific reading disability.” Orton favored the concept of “developmental” over “congenital,” as the former was thought to highlight both hereditary and environmental factors. Agreeing with Morgan and Hinshelwood regarding the absence of intellectual impediment in specific reading disability, he made extensive use of the Stanford-Binet Intelligence Scale in understanding literacy.

In terms of etiology, Orton did not agree with the angular gyrus hypothesis suggested earlier. Among other reasons, he noticed the lack of neuroanatomical evidence and argued that the complex cognitive processes of literacy cannot be linked to a single brain structure. Alternatively, he proposed that the syndrome could be due to a developmental delay of the language-specific left hemisphere resulting in mixed or incomplete cerebral dominance. This theory was based on observations of high incidence of atypical handedness and eyedness among reading-disabled individuals and their relatives. A high number of reversal errors in reading and spelling were taken as further support.

A considerable portion of Orton’s work was devoted to treatment of specific reading disability. He was confident that many of the affected individuals could improve their reading difficulties by training strategies that exploited auditory and kinesthetic senses, which did not seem to be impaired. Specifically, he advocated teaching the phonic equivalents for every letter of the alphabet and then working on the blending of the letter sounds. Tactile tracing of letters while sounding them out were assumed to support the learning process. This multisensory approach (see Hinshelwood, 1917) was elaborated on later by Anna Gillingham and Bessie Stillman (1936). Today, these practices are established as the Orton-Gillingham method, a phonics-based training using visual, auditory, and kinesthetic modalities for reading and spelling.

Neither word blindness nor *strephosymbolia* has become an accepted term in the dyslexia literature, however, primarily because of their focus on isolated, nonspecific fea-

tures of the disorder. Although Orton’s view of cerebral dominance did not meet unanimous agreement, his theoretical accounts had a sustained influence on the study and treatment of developmental dyslexia. The foundation of the International Dyslexia Association, originally named the Orton Dyslexia Society, has reflected Orton’s impact on the field.

Many approaches that followed this pioneering work are closely aligned with contemporary research and are discussed in more detail in the section titled “Etiology and Mechanisms.” Up to the 1970s, visual deficits were assumed to be at the core of children’s difficulty with written language. The influential studies of Isabelle Liberman and others (Fischer, Liberman, & Shankweiler, 1978; I. Y. Liberman, Shankweiler, Orlando, Harris, & Berti, 1971; see Vellutino, 1979) initiated a rethinking toward the idea that dyslexia is based on phonological deficits within the language processing system. However, in the past 3 decades the hypothesis that dyslexia is associated with impaired perceptual processes has been reconsidered. Several theories have been developed on the basis of auditory (Tallal, 1980) and visual (Lovegrove, Martin, & Slaghuis, 1986) deficits, cerebellar dysfunctions (Nicolson, Fawcett, & Dean, 2001), and general sensorimotor impairments (Stein, 2001). Extensive studies on neuroanatomical as well as neurophysiological correlates of dyslexia have been conducted since Norman Geschwind (1962; Geschwind & Levitsky, 1968) published his seminal work on cerebral asymmetry in the 1960s. Concerning the early observation that dyslexia tends to run in families, innovative methods to study the genetics of the disorder have led to novel theoretical accounts (see Grigorenko, 2001; Pennington, 1995; Schulte-Körne, 2001). Psychological as well as neurobiological approaches have inspired the development of tailored interventions (see Habib, 2003), which in turn have influenced current theorizing.

LANGUAGE LEARNING IMPAIRMENTS

The maxim of a developmental psychopathology perspective—the interplay between typical and atypical development—constitutes an important element in the study of language learning impairments. As outlined earlier, the issue of definition and phenomenology has been related to progress made in research addressing topics of etiology, therapy, and epidemiology. Conversely, diagnostic criteria have had a major impact on data collection and interpreta-

tion. This section thus introduces contemporary concepts of language learning impairments, followed by a comprehensive discussion of biological and psychological theoretical models of the disorder. Reviewing this literature, we focus on essential components of language and language learning, namely, basic sensory processing and phonology.

Definition: Specific Language Impairment

Children usually acquire language rapidly and with little apparent effort. Parents report that children understand words from about 8 months and start to produce words around their first birthday (Fenson et al., 1994). By the age of 2 to 3 years, most toddlers are speaking in short sentences that incorporate many aspects of the syntactic structures present in adult grammar (Bates, O'Connell, & Shore, 1987). Some children show slow progress during this early phase but catch up with the peer group at around 3 years. They are what have been called "late bloomers." Other children's language difficulties persist, leaving them at a disadvantage when formal education begins. When the language delay is significant and is not due to other clinical conditions, these children receive the diagnosis specific language impairment (SLI).

Most researchers and practitioners employ standardized language tests for assessing receptive and/or expressive language delay. Although there is variation across investigations and clinical settings, the delay required for this diagnosis is at least 1 standard deviation below the mean of normal (Tallal & Benasich, 2002). The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*; American Psychiatric Association, 1994) distinguishes between two categories of Developmental Language Disorder or SLI: Expressive Language Disorder affects language production, whereas Mixed Receptive-Expressive Language Disorder includes both language comprehension and production deficits. A similar distinction is made by the *International Classification of Diseases 10 (ICD-10*; World Health Organization, 1992). Here, the mixed type is labeled Receptive Language Disorder. Comprehension and/or production problems may manifest within one or more of the components of language, including phonology (organization of speech sounds), lexicon (word meaning), morphology (word formation), syntax (phrase and sentence formation), and pragmatics (interactive conversational skills). For instance, typical phonological problems observed in the speech of children and even adults with SLI are consonant cluster reduction (e.g., snow [no]) or final consonant deletion (e.g., boat [bo]; L. B. Leonard, 1998).

In particular, young children often meet criteria for Phonological/Specific Speech Articulation Disorder (*DSM-IV, ICD-10*), which refers to the difficulty in clearly and correctly producing one or more of the sounds in speech. The manifold language deficits present in SLI hence point to a heterogeneous group of children.

SLI is primarily a diagnosis made by the exclusion of other causes for delayed or deviant language. Mental impairment, hearing or other sensory deficits, neurological disease (e.g., seizure disorders, cerebral palsy, brain lesions), abnormalities of oral structure, Autism Spectrum Disorders, and lack of adequate opportunity are the most widely accepted exclusionary criteria (American Psychiatric Association, 1994; L. B. Leonard, 1998). At least three of these criteria, however, have limitations. First, exclusion of mental impairment is largely based on a nonverbal intelligence measure. A generally applied cutoff for diagnosing SLI rather than mental impairment is a nonverbal intelligence quotient (IQ) of 85. Some children with language problems, however, score in the borderline range (70 to 84) on a performance test; such values are considered too low for SLI but too high for a diagnosis of mental retardation. But even assessment of nonverbal IQ may be directly affected by language deficit as test instructions are usually verbal. Further, intellectual capacity appears to decrement somewhat with age in children diagnosed with SLI, probably due to the close link between general cognition and language abilities (Benasich et al., 1993). The more abstract abilities tested under the label of nonverbal IQ are less tightly linked with oral language abilities. However, differences in the amount of information received in the environment as a function of effortful interaction with adults as well as peers has a cumulative effect on the child's knowledge base. Other investigators stipulate a discrepancy of at least 1 standard deviation between nonverbal intelligence and verbal abilities to place a child in the SLI category with reasonable certainty. However, little difference has been observed in the profiles of SLI children with or without a significant discrepancy score (Tallal & Benasich, 2002).

Second, hearing problems may be the result of otitis media (middle ear infection) with effusion (fluid accumulation). During their preschool years, many children experience several episodes of ear infection without developing disturbances in language. Consequently, it is neither necessary nor sufficient to cause SLI, which led some authors to disregard otitis media with effusion as a straightforward exclusionary criterion (Rapin, Allen, & Dunn, 1992). Other researchers lowered the criterion to "no recent episodes"

(L. B. Leonard, 1998). Even in normal preschoolers, however, fluid in the middle ear can persist for many months. Diagnosis of SLI should therefore take into account the biographical and environmental context together with specific conditions, such as otitis media with effusion (Roberts, Burchinal, & Zeisel, 2002).

Third, conventionally SLI and Autism are regarded as distinct developmental disorders. Recently, this view has been challenged for several reasons (see Bishop, 2003): (1) SLI tends to cluster in families of individuals with Autism (Rapin, 1996a); (2) children with Autism display mixed receptive-expressive language dysfunctions similar to those seen in SLI (Kjelgaard & Tager-Flusberg, 2001; Rapin, 1996b); (3) enlargement of cerebral white matter and atypical cortical asymmetry have been found in both disorders (Herbert et al., 2004, 2005); and (4) some children exhibit characteristics intermediate between Autism and SLI (Bishop & Norbury, 2002). It has thus been suggested that both disorders are on a continuous spectrum rather than being discrete conditions (Herbert et al., 2004; Karmiloff-Smith, 1998). Alternatively, Bishop (2003) proposes regarding Autism as a form of SLI ("SLI plus"), in which a broader range of impairment is evident.

The exclusion of various disabling factors in the diagnosis of SLI does not rule out co-occurrence of other problems and clinical disorders. Children with SLI frequently show clumsiness or slow motor responses typical of younger children (e.g., American Psychiatric Association, 1994; Bishop, 1990; Bishop & Edmundson, 1987b; Stark & Tallal, 1988; Tallal, Dukette, & Curtiss, 1989). Enuresis (childhood incontinence), Attention-Deficit/Hyperactivity Disorder, and emotional problems such as anxiety and depression as well as social withdrawal are also not uncommon in SLI (e.g., American Psychiatric Association, 1994; Beitchman, Nair, Clegg, Ferguson, et al., 1986; Benasich et al., 1993). Yet, little is known about how these disturbances are related to SLI, or the neural mechanisms mediating the comorbidity.

Longitudinal research studying children with SLI either retrospectively or prospectively from the preschool years converge to demonstrate that oral language deficits often persist, usually in subtle form, into later childhood, adolescence, and, in several cases, adulthood (e.g., Aram, Ekelman, & Nation, 1984; Beitchman, Wilson, Brownlie, Walters, & Lancee, 1996; Bishop & Edmundson, 1987a; Stark et al., 1984; Tallal, Curtiss, & Kaplan, 1988; Tomblin, Freese, & Records, 1992). In a large-scale prospective study, Tallal et al. assessed 101 children with SLI annually for 5 years, beginning at age 4. The majority of children were receiving speech therapy and/or spe-

cial educational services in school. Although symptoms ameliorated across time, children with SLI were consistently outperformed by their nonimpaired peers across the entire set of spoken language tests. Throughout the study, the oral language profile of the affected group was reminiscent of that seen in normal developers 1 to 2 years younger.

In this vein, longitudinal studies on SLI frequently report a high incidence of poor academic achievement. Reading and spelling deficits pertinent to dyslexia are estimated to occur in 25% to 90% of classroom children with a preschool history of SLI (e.g., Bishop & Adams, 1990; Catts, 1993; Stark et al., 1984; Tomblin et al., 2000). Differences in definition of oral and written language disorders, age of initial diagnosis, length of follow-up, and sample recruitment may well account for the variation in figures. Recently, it was shown that the rate of literacy problems in SLI increased between the ages of 8 and 15 years; for reading accuracy, the increment was 37% across the 8-year interval, with a starting value of 6% (Snowling, Bishop, & Stothard, 2000). A study by Tomblin et al. suggests that the risk for reading disability is greater than the risk for behavioral problems among second graders with a preschool history of SLI. Moreover, the occurrence of behavioral disorders, such as attention deficits and externalizing problems, in SLI seems to be mediated by reading performance. What has not been well understood is the specific neurocognitive profile underlying the interaction of oral and written language difficulties. This issue is addressed when we turn to etiological models.

Definition: Developmental Dyslexia

Although symptoms of dyslexia may be present as early as preschool age, affected children are not diagnosed until they have tried and failed to learn to read. Especially in children demonstrating above-average intellectual ability, the disorder may not be manifest before the fourth grade, or even later (*DSM-IV*). According to the *ICD-10* manual, Specific Reading Disorder denotes problems in learning to read, spell, and write despite adequate intellectual capacity, educational resources, and social background. At the same time, sensory acuity deficits, neurological pathology, and psychiatric disease are absent. In the *DSM-IV*, dyslexia is coded as Reading Disorder, similarly emphasizing poor reading skills by the exclusion of extraneous factors.

Core symptoms in reading and spelling encompass omissions (e.g., "ply" instead of "play"), substitutions (e.g., "hand" for "finger"), inversions (e.g., "aks" instead of "ask"), or additions (e.g., "to" and "of") of words or

fragments of words. Decoding is frequently slow. Passage reading is associated with problems that dyslexic children have keeping their place in lines of text, as are errors in comprehension. At the beginning of first grade, there may be weakness in learning the alphabet, naming letters, producing rhymes, and categorizing speech sounds. In secondary school and adulthood, deficits in spelling often are more salient than reading problems (*ICD-10*). Generally, frequency and type of errors in literacy components vary as a function of skills learned and the difficulty of the task (Grissmann, 1972).

Preceding and accompanying poor literacy skills, the disorder often manifests in various sensorimotor and cognitive dysfunctions, including problems in fine motor coordination (e.g., tying shoelaces), clumsiness, poor visual discrimination, weakness in auditory segmenting, limitations in working memory, linguistic disturbances (e.g., misarticulation of sounds, deficits in language comprehension and/or production), or a combination of these (*DSM-IV*, *ICD-10*). It is not uncommon for dyslexia to accompany psychosocial problems and clinically relevant conditions. As described in *DSM-IV* and *ICD-10*, dyslexic children may suffer from demoralization, low self-esteem, and deficient social skills. Problems in school adjustment or even an increased risk for dropping out of formal schooling have been reported. Adult dyslexics may have significant problems in occupational functioning and social adjustment. The disorder is also often related to a higher rate of Attention-Deficit/Hyperactivity Disorder, conduct problems, and emotional disturbances. A longitudinal study by Fergusson and Lynskey (1997) demonstrates that the co-occurrence of conduct problems and reading difficulties arise because reading-delayed children are characterized by disadvantageous features that were already present at preschool age. A person's general intellectual ability, amount of support received, and socioeconomic status have been suggested as factors influencing the course of dyslexia (Naylor, Felton, & Wood, 1990). Nevertheless, research has shown that problems of the dyslexic population may persist into adulthood (Boetsch, Green, & Pennington, 1996; Maughan, 1995; Undheim, 2003).

Standard definitions of dyslexia imply impairment in special achievement (*DSM-IV*, *ICD-10*). To be diagnosed as dyslexic, a child's reading and spelling skills should significantly fall below the performance expected given his or her age, intelligence, and educational level. In the *ICD-10* research criteria, a discrepancy of at least 2 standard deviations between achievement and both age norm and general IQ is recommended. However, it is commonly intelligence

that has received the most attention in diagnostics and research. Because a 2 standard deviation achievement-IQ discrepancy would exclude a large percentage of dyslexic individuals, in many studies, the criterion has been lowered to 1 to 1.5 standard deviations (see Schulte-Körne, Deimel, & Remschmidt, 2001, for discussion).

Over the past decade, the definition and use of the term *dyslexia* has been controversial as several researchers have argued that the conventional discrepancy model is empirically unfounded and theoretically inadequate (e.g., Aaron, 1997; Fletcher et al., 1998; Gustafson & Samuelsson, 1999; Stanovich, 1996). For instance, the relationship between intelligence and reading has proved ambiguous in that only 16% to 25% of the variance in decoding can be accounted for by IQ (Aaron, 1997; Gustafson & Samuelsson, 1999). Reading disability may have a detrimental effect on IQ test performance, as poor readers spend less time in reading activities and therefore often exhibit limited knowledge and a decline in language skills (Aaron, 1997). More globally, verbal IQ may decrease as a consequence of dysfunctional and effortful reading, a phenomenon known as the "Matthew effect" (Stanovich, 1986). Also, no difference in reading-related tasks has been observed between reading-impaired children showing high or low IQ, which indicates that they might similarly benefit from intervention techniques (Gustafson & Samuelsson, 1999; Stanovich, 1996).

The functional significance of the discrepancy definition is that children with an IQ in the borderline (70 to 84) range who cannot learn reading and writing are not considered dyslexic. They are sometimes labeled "backward readers" (Rutter & Yule, 1975), "garden-variety poor readers" (Stanovich, 1991), or "low achievers" (Fletcher et al., 1994). In most countries, these children are not eligible for special educational services because their failure to initiate reading and spelling is accounted for by their general pattern of performance.

To summarize, both dyslexia and SLI may reflect a heterogeneous group of disorders. After reaching school age, children with SLI are at risk for learning problems similar to those seen in dyslexics; conversely, children with developmental dyslexia typically have been found to be deficient in some linguistic tasks (e.g., Aram et al., 1984; Bishop & Adams, 1990; Catts, 1993; Flax et al., 2003; Scarborough, 1990; Tallal et al., 1988; Tomblin et al., 2000). On the basis of such performance profiles, it has been proposed that dyslexia, at least for some dyslexics, may be a less severe form of SLI (Kamhi & Catts, 1986). Although there is supporting evidence from behavioral as well as neurobiological studies (see section on Etiology and Mechanisms), this assumption is still a matter of intense debate (L. B. Leonard,

1998; Snowling et al., 2000). Nevertheless, the striking convergence between the characteristics of developmental dyslexia and SLI has given rise to the classification language learning impairment (LLI; Tallal, 2004).

Prevalence Estimates: Specific Language Impairment

Epidemiological work indicates that nearly 20% of pre-school- and school-age children have some form of language deficit. The majority of childhood language problems are related to other primary conditions, such as hearing loss, mental retardation, or neurological disease (Beitchman, Nair, Clegg, Patel, et al., 1986). In a large-scale project including more than 7,000 children, Tomblin et al. (1997) observed that 7.4% of 5- to 6-year-olds experienced significant delays in language of unknown origin. This is a higher prevalence rate of SLI than previously expected. Interestingly, more than 70% of these children met the research criteria for SLI (inter alia language skills at least 1.25 standard deviations below population average) but have never been diagnosed based on reports of parents, physicians, or teachers. In line with those figures, the *DSM-IV* manual provides estimates of 3% to 5% for children having Expressive Language Disorder and 3% for children suffering from both receptive and expressive deficits.

A number of studies have shown that SLI occurs across generations. The affectance rate in families with a history of SLI is roughly 20% to 40% (e.g., Flax et al., 2003; Lahey & Edwards, 1995; Neils & Aram, 1986; Tallal et al., 2001; Tallal, Ross, & Curtiss, 1989a; Tomblin, 1989). Using direct testing methods, Tallal et al. (2001) found that 30% of the children diagnosed with SLI (ages 4 to 14 years) had affected primary relatives (parents and siblings), compared to 7% of the control children. In a similar vein, Flax et al. report elevated rates of both SLI and reading impairment in immediate and extended family members (viz., 25% and 23%, respectively), with a high degree of co-occurrence of the disorders (46%) in affected individuals.

SLI is more prominent in males than in females; the ratio is approximately 2:1 to 3:1 (e.g., Bishop, 1997; Flax et al., 2003; R. B. Johnston, Stark, Mellits, & Tallal, 1981; Tallal et al., 1989b; Tomblin, 1997; Tomblin & Buckwalter, 1994). This imbalance has also been observed in a prospective family study by Choudhury and Benasich (2003). Here, 41% of boys as compared to 16% of girls born into families with a history of SLI were affected. On the other hand, Rice, Haney, and Wexler (1998) did not find gender differences in families of language-impaired individuals. An issue raised in this regard is the ascertainment bias, with

more boys than girls receiving a diagnosis given the higher incidence of attention and behavioral problems in boys (Benasich et al., 1993).

Prevalence Estimates: Developmental Dyslexia

Dyslexia is the most common learning disability, affecting around 3% to 10% of Western populations (e.g., American Psychiatric Association, 1994; Esser & Schmidt, 1994; Miles, 2004; Rutter, Tizard, Yule, Graham, & Whitmore, 1976; S. E. Shaywitz, Shaywitz, Fletcher, & Escobar, 1990). Figures as high as 17% have been reported among regular classroom children in North America (S. E. Shaywitz & Shaywitz, 2001). In Asian countries, dyslexia rates are estimated at 1% to 5% (Leong, Nitta, & Yamada, 2003; Tarnopol & Tarnopol, 1981). However, it may well be the case that this is an underestimate of actual prevalence due to low ascertainment (Leong et al., 2003; Leong & Tan, 2002). Variations in prevalence levels are thought to arise from several factors involving language characteristics, cultural expectations, investment in literacy education, diagnostic assessment, variants of dyslexia (milder versus severe cases), and sample size (Lovett, 1992; Miles, 2004). For instance, alphabetic languages vary in degrees of phonic regularity. English consists of 40 speech sounds or phonemes, which can be spelled in 1,120 different ways. In contrast, Italian speakers need to map only 25 phonemes to 33 letter combinations or graphemes (Hel-muth, 2001). Whereas the English orthography demands a great deal of the learning individual, an Italian child with dyslexia may master the more regular phoneme-grapheme correspondences in his or her language (albeit memorization of the correspondence rules may be prolonged, as decoding speed is commonly reduced). Likewise, written Japanese provides highly consistent (Kana) syllabograms, and its nonalphabetic (Kanji) ideograms offer possibilities for whole-unit responses (H. W. Stevenson et al., 1982).

Substantial evidence continues to accrue that dyslexia aggregates in families (see Grigorenko, 2001). Pennington (1995) reviewed four family studies, finding that recurrence rates for siblings and parents ranged from 39% to 43% and 27% to 49%, respectively. An extended comparison across eight studies, in which parents of dyslexic children were examined, showed a median incidence rate of 46% among fathers and 33% among mothers (Scarborough, 1998). Posterior probability estimates indicate that the median increase in risk to a child having a dyslexic parent is about 8 times the population probability of 5% (Gilger, Pennington, & DeFries, 1991). A similar magnitude has

been observed in a longitudinal study from before kindergarten to the end of second grade (Pennington & Lefly, 2001). Here, 34% of the children from families with a history of reading disabilities compared to 6% from control families developed dyslexia.

A core topic in dyslexia is the notion that male children are affected more frequently than females. Although several epidemiological studies have found dyslexia to be about 2 to 4 times more common in boys than in girls (Finucci & Childs, 1981; Flannery, Liederman, Daly, & Schultz, 2000; C. Lewis, Hitch, & Walker, 1994; Rutter & Yule, 1975), others have demonstrated a more balanced gender ratio (Flynn & Rahbar, 1994; S. E. Shaywitz et al., 1990; Wadsworth, DeFries, Stevenson, Gilger, & Pennington, 1992). This difference has been attributed to referral bias (i.e., problems in boys being more salient than in girls), but recent work based on large samples (Rutter et al., 2004) comes to the conclusion that reading disabilities are clearly more prominent in boys than in girls.

ETIOLOGY AND MECHANISMS

Over the past 2 decades, evidence supporting a continuum between oral and written language impairments has continued to mount. These investigations showed that children classified as SLI and those having a diagnosis of dyslexia manifest a variety of sensory and motor problems as well as linguistic deficits, particularly in the area of phonology and grammatical morphology (see Bishop & Snowling, 2004; L. B. Leonard, 1998). Whether these commonalities derive from speech-specific mechanisms or more basic processing deficits is currently the center of theoretical debate. Added to this picture are neurobiological models involving studies on the neuropathology of LLI as well as animal research. Evidence pointing to family aggregation of both disorders has led to a body of heritability research, including pedigree, twin, and gene linkage investigations.

Psychological Models

Considerable attention has been focused on trying to understand the neurocognitive determinants of LLI, using models derived from the cognitive neurosciences to inform developmental psychopathology in terms of etiology. Given the lack of homogeneity among children showing delayed oral and written language development, it is unlikely that a single etiology will be found. Several theories of the etiology of SLI and dyslexia have been put forward in the literature,

but no consensus for the cause of both disorders is agreed on. We limit our review to hypotheses pertaining to processing deficits in specific mechanisms, particularly phonological and basic sensory skills. For a survey of accounts on disturbances in nonphonological parameters of language, such as grammatical knowledge, the reader is referred to L. B. Leonard (1998) and Bishop and Snowling (2004).

Phonological Processing Deficit

Impaired phonological processing has been frequently put forward as a core deficit in developmental dyslexia (Goswami, 2000; Snowling, 2001; Wagner & Torgesen, 1987). Phonological processing refers to “the use of phonological information (i.e., the sounds of one’s language) in processing written and oral language” (Wagner & Torgesen, 1987, p. 192) and encompasses at least three components: phonological or phonemic awareness, phonological retrieval, and phonological short-term memory.

Phonological awareness is defined as “conscious access to the phonemic level of the speech stream and some ability to cognitively manipulate representations at this level” (Stanovich, 1986, p. 362). Research on typical language acquisition has demonstrated that very young children use holistic representations of words. As they grow older, children begin to segment sounds in words, namely, syllables (gar-den) and onset rhymes (br-ush, s-eet). The ultimate representation at the level of the individual phoneme is believed to depend on being taught an alphabetic script. Such children would be aware that, for example, *cat* and *act* are composed of the same phonological elements (Boucher, 1994; Jusczyk, 1993; Metsala & Walley, 1998). This pattern of development has been found to occur across languages (Goswami, 2000).

Phonological awareness tasks involve counting, deleting, and substituting phonemes within words, reversing the order of phonemes within words, blending phonemes presented in isolation to form a word, and segmenting words into phonemes. Other tasks are concerned with awareness of broader sound structures; these encompass rhyming skills, counting or deleting syllables within words, and segmenting words into intrasyllabic units (Rack, 1994; Wagner & Torgesen, 1987). The former skills have been referred to as phonological awareness in the narrow sense, the latter as phonological awareness in the broad sense (Skowronek & Marx, 1989).

In their classic study, Bradley and Bryant (1978) presented 10-year-old dyslexic children with rhyme and alliteration tasks. The children were required to indicate which was the odd one in a sequence of four spoken words (e.g., *weed peel need deed* or *nod red fed bed* or *sun see sock rag*).

Dyslexic children performed less well than younger reading-level-matched controls. This suggests that poor rhyme and word-onset awareness may have a role in their reading impairment. Further evidence was reported by Rack (1985), who found that dyslexic children have difficulty in simple rhyme judgments.

A large body of work shows that children with dyslexia are impaired on a variety of phonological awareness skills in the narrow sense (e.g., Bruck, 1992; Fawcett & Nicolson, 1995; Joanisse et al., 2000; Olson, Wise, Conners, & Rack, 1990; Swan & Goswami, 1997). The dyslexic children were not only outperformed by their age-matched controls, but were worse when compared with younger reading-level-matched normal developers. Thus, performance on these phonological awareness tasks was not simply a function of reading level.

In a similar vein, poor awareness for various linguistic units has repeatedly been documented in SLI (e.g., Bird, Bishop, & Freeman, 1995; Joffe, 1998; Leitão, Hogben, & Fletcher, 1997; Snowling et al., 2000). Also, deficits in phonological awareness have been found to be related to reading impairment in a variety of these investigations.

There is substantial evidence demonstrating that preschool phonological awareness predicts later reading achievement across alphabetic writing systems (e.g., Bradley & Bryant, 1983, 1985; Lundberg, Olofsson, & Wall, 1980; Marx, Jansen, Mannhaupt, & Skowronek, 1993; Wagner, Torgesen, & Rashotte, 1994). For instance, Bradley and Bryant conducted a 4-year longitudinal study providing data from 368 children ages 4 to 5 years at initial screening. Phonological awareness was measured using the rhyme-oddity task (see earlier); the 4-year-olds listened to series of three words, the 5-year-olds to series of four. Results indicate a significant relationship between preliterate children's awareness of rhyme and word onsets and subsequent performance on reading and spelling tests. When age at initial testing and general cognitive ability were controlled, rhyming and alliteration skills explained 4% to 10% of the variance in reading and 6% to 8% of the variance in spelling. This seemed to be specific, as rhyme-oddity detection accounted for less of the variance (1% to 4%) in later math ability.

In a quantitative meta-analysis of controlled U.S. studies, Bus and van IJzendoorn (1999) showed that training of phonological awareness reliably improves children's phonological and reading skills. The combined effect sizes for phonemic awareness and reading were 0.73 ($n = 739$) and 0.70 ($n = 745$), respectively. As noted by the authors, approximately 500 studies with null results would be required

to turn this finding into nonsignificance. Thus, phonological awareness should be considered an important condition for early reading.

Phonological retrieval denotes the ability to access the lexicon by utilizing sound-based representations. It seems to be especially important at early stages of reading acquisition and even useful in the sophisticated reader for less familiar or unknown words (Wagner & Torgesen, 1987). Phonological retrieval is typically assessed through measures of naming accuracy and speed. The classic rapid automatized naming (RAN) task entails the naming of familiar items under timed conditions. Denckla and Rudel (1976) found dyslexic children to perform more slowly on series of objects, colors, digits, and letters compared to both age controls and nondyslexic learning-disabled individuals. Subsequent RAN studies confirm that dyslexic children exhibit deficiencies in naming speed (Bowers & Swanson, 1991; Goswami et al., 2002; Lovett, 1987; Semrud-Clikeman, Guy, Griffin, & Hynd, 2000; Wolf, Bally, & Morris, 1986). Several researchers observed prominent differences for reading-age-matched comparisons (Ackerman & Dykman, 1993; Wimmer, 1993; Wolf, 1991; Wolf & Segal, 1999). RAN tasks have also been shown to distinguish SLI children from normal developers (Catts, 1993; Katz, Curtiss, & Tallal, 1992; Leitão et al., 1997). Katz et al., for instance, reported RAN speed to be significantly associated with reading abilities in both language-impaired and control subjects. Moreover, both groups demonstrated an increase in naming speed between the ages of 4 and 8 years. A similar result was obtained in reading-disabled children, suggesting that processes tapped by RAN tasks become more automatized with maturation (Watson & Willows, 1995; Wolf et al., 1986).

Various studies concede the predictive value of preschool RAN performance for early reading achievement (e.g., Catts, 1993; Wolf et al., 1986). The findings by Wolf et al. indicate that the relationship of speeded naming to reading is mediated by the subject's age and stimulus type. Whereas nongraphological RAN symbols (i.e., objects and colors) lost their predictive power at the time children entered elementary grades, naming rate for graphological symbols (i.e., letters and digits) continued to predict word reading scores.

Some authors have suggested that deficits in RAN speed are not inherently phonologic, but rather reflect a general impairment in automatizing low-level subprocesses involved in reading (Wolf, 1991; Wolf & Bowers, 1999; Wolf et al., 2002). Wolf and Bowers propose that problems in phonological awareness and RAN are separable sources of

reading impairment. This so-called double-deficit hypothesis predicts three categories of reading-disabled individuals: the phonological-deficit reader, who encounters poor phonological awareness skills with otherwise intact naming speed; the rate-deficit reader, exhibiting the precisely reversed profile; and the double-deficit reader, showing a deficiency in either process. Phonological-deficit readers are specifically impaired in word-identification accuracy, rate-deficit readers tend to be slower in word decoding, and double-deficit readers exhibit a general dysfunction on all decoding measures. Although this literature is not conclusive, both dimensions appear relatively independent and additive (Compton, DeFries, & Olson, 2001; Wolf et al., 2002). Supportive evidence emerges from studies examining naming speed and phonological awareness in regular orthographies, such as Dutch (van den Bos, 1998) and German (Wimmer, 1993). For instance, Wimmer found that German fourth graders with dyslexia were at the same level as reading-level-matched second graders on phonological awareness tasks. In contrast, dyslexic subjects showed slower RAN performance than the younger controls. A similar pattern held true for word and pseudoword reading: Dyslexic children displayed high decoding accuracy, although they experienced marked speed decrements. This finding is striking with respect to pseudowords, that is, arbitrary letter strings that can be pronounced as if they are real words. Pseudoword decoding indicates to what extent a child has mastered grapheme-phoneme mapping, a task that English dyslexic children find very difficult (see Rack, Snowling, & Olson, 1992).

Phonological short-term memory can be conceived as forming sound-based representations of written symbols being sustained for a period of time. Efficient phonetic recoding appears to be an important tool for the novice reader. Unlike the able reader, the beginner devotes the maximum amount of cognitive resources possible to the process of blending phonemes to generate words (Wagner & Torgesen, 1987). Serial recall of diverse speech materials, digit and word span, and verbal repetition of words, pseudowords, or sentences exemplify measures of phonological short-term memory (Rack, 1994; Wagner & Torgesen, 1987). Early studies have shown that elementary school children with difficulty in word recognition tended to make more errors in serial-recall tasks, including spoken letter names (Shankweiler, Liberman, Mark, Fowler, & Fischer, 1979), consonant-vowel syllables (Brady, Mann, & Schmidt, 1987), and words (Brady, Shankweiler, & Mann, 1983; Mann, Liberman, & Shankweiler, 1980), as compared to their normal-reading peers. Poor readers were also

distinguished from good readers regarding their memory for printed letter strings (Shankweiler et al., 1979). In addition, poor readers were found to show a reduced or even absent phonological similarity effect (i.e., superior recall performance for phonemically dissimilar versus rhyming items) that is evident in normal individuals even at early reading stages (e.g., Brady et al., 1983; Mann et al., 1980; Shankweiler et al., 1979). These findings suggest that poor readers do not rely on codes in phonological short-term memory. However, it was subsequently demonstrated that poor readers show a phonological similarity effect comparable to normal controls when they (1) were presented with list lengths adjusted to their memory spans (Hall, Wilson, Humphreys, Tinzmann, & Bowyer, 1983; Holligan & Johnston, 1988), (2) were comparable or equated on memory span (Irausquin & de Gelder, 1997; R. S. Johnston, Rugg, & Scott, 1987), or (3) were matched on reading level (Holligan & Johnston, 1988; R. S. Johnston et al., 1987). This indicates that poor readers use phonetic recoding in short-term memory, but less efficiently, and hence have more limited capacity to remember linguistic material.

A wealth of studies has used pseudoword repetition to investigate phonological memory in developmental language disorders. Limitations in pseudoword repetition have frequently been shown in both SLI (e.g., Bishop, North, & Donlan, 1996; Botting & Conti-Ramsden, 2001; J. Edwards & Lahey, 1998; Gathercole & Baddeley, 1990; Montgomery, 1995; Snowling et al., 2000) and dyslexia (e.g., Kamhi & Catts, 1986; Snowling, 1981; Snowling, Goulandris, Bowlby, & Howell, 1986; van Daal & van der Leij, 1999). For instance, Snowling and colleagues (Snowling, 1981; Snowling et al., 1986) found dyslexic individuals performing worse than reading-level-matched controls. As for SLI, Kamhi, Catts, Mauer, Apel, and Gentry (1988) reported specific decrements in performance as a function of the number of syllables contained in pseudowords. From a theoretical perspective, Gathercole and Baddeley (1993) conjectured as to the role of phonological memory as a common factor affecting acquisition of vocabulary and grammar. Moreover, ability on pseudoword repetition predicts literacy achievement later in life.

In summary, there is substantial evidence that particular children with dyslexia, but also children having SLI, are affected by phonological processing deficits. Recently, a more general picture has emerged, viewing phonological deficits in the context of other variables. First, phonological skills often remain deficient into adulthood and even exist in individuals whose early language problems have resolved (e.g., Bishop et al., 1996; Bruck, 1992; Elbro,

Nielsen, & Petersen, 1994; Gallagher, Laxon, Armstrong, & Frith, 1996; Pennington, Van Orden, Smith, Green, & Haith, 1990). Second, the relationship between phonological skills and literacy appears to be reciprocal in nature. Wagner et al. (1994) assessed indices of phonological processing and reading-related knowledge from kindergarten through second grade. Although there were considerable influences of phonological abilities on word decoding, letter-name knowledge exerted a moderate effect on phonological skills. Third, the underlying mechanism of phonological impairments is still unclear. An integrating account derived from developmental theories of spoken word recognition maintains that language difficulties arise from poorly specified phonological representations (Goswami, 2000; Snowling, 2001). However, its causal primacy is under debate as well. Contrary to the proponents of the phonological deficit hypothesis, others hold the opinion that such problems are secondary to a more fundamental auditory processing deficit (Farmer & Klein, 1995; Tallal, 2004). This approach is discussed next.

Auditory Rate Processing Deficit

Research on auditory processing in language-based learning disorders has been particularly influenced by the work of Tallal and colleagues. Their model emphasizes the role of timing in the auditory system. The rate of information processing is considered essential for encoding brief and rapidly changing or rapidly occurring successive events (Tallal, 1984). Originally, Tallal's research focused on children with SLI. However, it was the striking similarity between SLI and dyslexia that led her to assume that the auditory deficit may be causally related to both conditions. Hence, low temporal sensitivity in the auditory system is assumed to be associated with difficulties in forming segmental phonological representations (Tallal, 2004).

Tallal and Piercy (1973a, 1973b, 1974, 1975) reported data from SLI children ranging from 7 to 9 years and age-matched normal developers. In the first study, Tallal and Piercy (1973a) used two different complex tones having a duration of 75 ms. The children learned to associate each specific isolated tone with a specific response panel. Subsequently, sequences of two tones (high-high, high-low, low-high, or low-low) were presented, and the child was asked to push the respective panels in the correct order. The SLI children performed above chance level when the tones were separated by an interstimulus interval (ISI) exceeding 300 ms, but their performance deteriorated when shorter ISIs were used. The controls maintained high-level performance at shorter ISIs and scored at above-chance levels with ISIs as brief as 8 ms. A similar pattern of

results was demonstrated when the child was asked to indicate whether two tones in a series were the same or different. This suggests that the sequencing difficulty experienced by the children with SLI was secondary to their impairment in discriminating rapidly occurring tones.

In a second study, Tallal and Piercy (1973b) manipulated the tone duration in addition to the ISI. When the tone duration was 250 ms, the SLI children repeated the two-element patterns as accurately as the control children throughout ISIs (8 to 428 ms). When the tone duration was 175 ms, the SLI children were outscored by the controls at short ISIs of 15 ms or less. Tones of 125 ms or 75 ms differentiated the two groups even for ISIs as long as 150 ms. Thus, the total duration of the stimulus pattern appeared to be critical to the SLI children's performance. Tallal and Piercy concluded that children with SLI exhibit a deficit in perceiving auditory events, which occur on a time scale of 10s of milliseconds. These temporal characteristics led the researchers to focus on the phonemic level of speech. Consonant and vowel phonemes are perceived by different temporally coded acoustic cues (e.g., A. M. Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967). The acoustic cue for vowels is the relation among the frequencies (called formants), remaining uniform throughout the stimulus duration. Stop consonants,¹ in contrast, are characterized by brief transitional periods during which the frequencies of the formants change very rapidly over time. Figure 7.1 illustrates the acoustic spectra of sounds that are perceived as the vowel phonemes /a/ and /ae/ (Figure 7.1 left) and the stop consonant-vowel syllables /ba/ and /da/ (Figure 7.1 right). The formant frequencies of the two vowels are stationary and differ from each other by a constant amount throughout their entire 150-ms duration. The two syllables share identical stationary formants of the vowel /a/ for most of the 240 ms and differ only in the initial portion, during which the frequencies change within some 40 ms. Consequently, the perception of a difference between stop-consonant syllables crucially depends on the accurate analysis of the very brief formant transitions.

Given the phonemes' temporal characteristics, Tallal and Piercy (1974) hypothesized that children with SLI would be (1) unimpaired in distinguishing the vowel phonemes /E/ and /ae/ of 250 ms, and (2) impaired in distinguishing the stop consonant-vowel syllables /ba/ and

¹ Stop consonants or plosives are produced by closing the vocal tract. Most languages have six stop consonants in common: b, d, g, p, t, k. The first three stops are voiced (i.e., they cause vibration of the vocal cords), the second three are unvoiced (i.e., vocal cords are not vibrating; e.g., A. M. Liberman et al., 1967).

Figure 7.1 Sound spectrograms of vowels /a/ and /ae/ (left) and stop consonant-vowel syllables /ba/ and /da/ (right). Component frequencies (in kHz) are represented on the ordinate, and time (in ms) is shown on the abscissa. Intensity is coded by the darkness of the traces (see text for details).

/da/. The latter have a total duration of 250 ms and a formant transition period of 43 ms. Tallal and Piercy observed no differences between SLI and control groups in sequencing the two vowels. In contrast, each control child succeeded in distinguishing /ba/ and /da/, but only 2 out of 12 SLI children could discriminate and sequence the syllables correctly.

In a study concluding this series, Tallal and Piercy (1975) examined whether SLI children's poor performance on tests with stop-consonant syllables was due to an inability to utilize brief cues within phonemes or was due to impairment in processing transitional speech elements. Children were presented with two pairs of synthesized speech stimuli: (1) the vowel-vowel pairs /EI/ and /aeI/, in which the first (stationary) vowel was 43 ms in duration, followed by the second vowel (207 ms duration); and (2) the consonant-vowel pairs /ba/ and /da/, in which the initial transitional period was extended from 43 ms to 95 ms and the duration of the stationary vowel was reduced to 155 ms. The SLI children displayed problems with the temporally reduced vowel-vowel syllables, but performed as accurately as the age controls did on the temporally extended stop-consonant pairs. This lends support to the notion that the brevity of the contrastive information represents a core variable in SLI children's sound difficulties. Remedial implications are discussed later.

Using an expanded set of synthesized syllables, Tallal and Stark (1981) added evidence that vowel and consonant confusions could not solely be attributed to the duration of

acoustic cues. Instead, problems appear to be greatest when brief stimuli are followed by rapid successive information.

The question arises as to the relevance of the auditory rate processes for perception of more complex speech stimuli. Tallal, Stark, Kallman, and Mellits (1980b) administered a perceptual-constancy task,² which required the child to push one panel for stimuli comprising the phoneme /b/ (/ba/, /be/, /bi/), and another panel for stimuli comprising /d/ (/de/, /dae/, /di/). Forty-one percent of the SLI children versus 63% of the controls managed the task. Those who succeeded participated in another task (Tallal, Stark, Kallman, & Mellits, 1980a) in which bisyllabic words were approximated by presenting the syllables adjacent in time (e.g., /dae/ 50-ms interval /di/, for *daddy*). Again, children with SLI had greater difficulty in sequencing the syllables than did the controls. The authors concluded that the added linguistic redundancy of the stimulus material was not sufficient to counteract the auditory processing deficit observed in children with SLI.

Phonetic analyses of language output data from SLI children versus age controls have shown a remarkable similarity

²In speech, perceptual constancy refers to the ability to detect acoustic information that remains constant over changes in phonetic context, characteristics of the speaker (e.g., gender), and speaking rate (A. M. Liberman et al., 1967; Strange, Jenkins, & Johnson, 1983). Perceptual constancy for the phonemes /b/ and /d/ occurring in various vowel environments (i.e., phonetic context) was assessed in the Tallal et al. (1980b) study.

between profiles of auditory processing constraints and speech production problems (Stark & Tallal, 1979). Production errors specifically occurred in voicing (e.g., voiceless [p] for voiced /b/ in word/syllable final position), followed by errors in place of articulation (e.g., alveolar [d] for velar /g/ in word/syllable initials). Parallels have also been drawn between rate processing in other sensory modalities (visual, tactile, and cross-modally) and data from motor tasks. Stark and Tallal (1988) reported that children with SLI were impaired in their ability to discriminate, sequence, or remember any brief stimulus (verbal or nonverbal) that was followed rapidly by another event, regardless of the modality of presentation. A similar performance profile was observed for the production of rapid, sequential oral or manual movements, regardless of whether the stimuli were verbal or nonverbal. Thus, rate processing deficits may not be specific to the auditory modality. Moreover, Tallal, Stark, and Mellits (1985) demonstrated the role of timing well beyond the domain of low-level speech processing. The degree of poor temporal integration in the auditory system was significantly correlated with the degree of language comprehension deficits.

In summary, many children with SLI have difficulty with tasks involving rapid auditory processing, though at least some of these children exhibit impaired frequency discrimination abilities as well (Stark & Heinz, 1996; Tallal & Stark, 1981). Furthermore, some children with SLI have been reported to be impaired in sequencing more slowly presented sounds (Bishop, Bishop, et al., 1999; Tallal, Stark, Kallman, & Mellits, 1981), possibly pointing to a more general auditory deficit. There is also empirical evidence that temporal constraints are present in other sensory modalities as well as motor systems (Katz et al., 1992; Stark & Tallal, 1988). This may have significant implications for theories on neurocognitive mechanisms underlying speech in humans.

The same series of auditory tasks as used in the Tallal and Piercy (1973b, 1974) studies was administered to children diagnosed with dyslexia. Tallal (1980) observed that 10-year-old dyslexics performed as well as younger normal developers when the tones were presented slowly (428 ms ISI), but did less well when the presentation rate was increased (ISIs declining from 305 to 8 ms). Their errors in auditory rate processing were found to correlate significantly with errors in tests of spelling ($r = .67$), word discrimination ($r = .64$), word knowledge ($r = .64$), and pseudoword reading ($r = .81$). The last correlation is of particular importance as it supports an association between auditory rate processing and phonological decoding (i.e.,

the use of grapheme-phoneme conversion rules). Tallal concluded that the auditory dysfunction might disrupt the ability to learn to use phonetic codes adequately.

Reed (1989) confirmed and extended the findings of Tallal (1980) in dyslexic second- and third graders versus age-matched controls. Sequencing performance at varying ISIs was assessed using pairs of vowels and stop consonant-vowel syllables with a duration of 250 ms as well as pairs of complex tones with a duration of 75 ms. Dyslexics' performance decreased as a function of ISI length (declining from 400 to 10 ms) for tones and consonant syllables. As predicted, they performed within the normal range when vowels were used. The difficulty with brief and rapidly changing cues and mastery with long-duration stimuli were also observed in tasks simulating natural speech conditions: Performance was poor when they were asked to match pictures with auditory words differing in their initial stop consonant, but they had no unusual problems in sequencing long vowels embedded in white noise. Reed also examined whether rate processing deficits and phonological impairments are characteristic of the same individuals with dyslexia. Children participated in a categorical perception task, which entailed a nine-item continuum varying from /ba/ at one end point to /da/ at the other end point. Dyslexics were impaired in discriminating syllable pairs that cross the phonetic boundary. Additionally, they were less consistent than normal readers in identifying syllables near the /ba/-/da/ boundary. Thus, dyslexic children exhibited less sharply defined categorical borders. The perceptual difficulty with brief and rapidly changing cues might contribute to inadequately defined sound representations and hence interfere with the processing of phonological information.

This work indicates that auditory rate dysfunction is present in children with dyslexia, as it might be co-occurring with a phonological deficit. However, Tallal (1980) observed that performance in pseudoword reading and auditory rate processing varied considerably within the dyslexic group. Fifty-five percent of the dyslexics scored within normal limits when presented with rapid successive tones, and 45% showed a similar, albeit less impaired, pattern of performance as that found in SLI children (Tallal & Piercy, 1973b). Tallal inferred two subgroups of dyslexia: one group with concomitant oral language delay, who exhibit both deficits in temporal processing and "phonics skills," and another group with normal language skills showing none of these deficits. In line with this notion, Tallal and Stark (1982) reported that dyslexic children without oral language delay differed from normal readers neither in

sequencing rapid tones nor in their knowledge of word parts, which is a measure of phonics skills. However, to completely support Tallal's subgroup hypothesis, dyslexic children having normal oral language should be compared with both normally developing peers and dyslexics suffering from concomitant oral language weakness. This study was carried out by Heath, Hogben, and Clark (1999), whose findings provide no direct evidence for the subgroup's profile proposed by Tallal.

Dyslexia has also been associated with a cross-modal rate processing deficit (see Farmer & Klein, 1995). The empirical evidence for the co-occurrence of visual and auditory impairments is not conclusive, however. For instance, Van Ingelghem et al. (2001) reported that 7 out of 10 dyslexic children had higher thresholds than normal readers both for auditory and visual gap detection. In contrast, Heim, Freeman, Eulitz, and Elbert (2001) found high-level visual performance in a small group of dyslexic children showing impaired discrimination of rapidly changing stop consonant-vowel syllables. The conflicting results could either be sample related and/or task related (V. T. Edwards et al., 2004; Fitch & Tallal, 2003). Another possibility is that the findings are moderated as a function of age, with visual deficits disappearing through development in certain individuals with LLI (Di Lollo, Hanson, & McIntyre, 1983; Tallal et al., 1981). To test this hypothesis, Heim, Keil, and Ruf (2005) compared two age groups on tasks measuring auditory and visual rate processing. Auditory performance was assessed by means of a syllable-discrimination task; visual performance was indexed by judgments of temporal order of lightness changes. Dyslexic children exhibited higher visual thresholds than the controls did. This was in contrast to what was observed in older participants. Both young (11-year-old) dyslexics and older (13-year-old) controls demonstrated no relationship between auditory accuracy and visual thresholds. In contrast, significant relationships were found in the young control and older dyslexic group. The findings suggest the co-occurrence of visual and auditory impairments in young children with dyslexia. Visual processing deficits, however, seem to recover across development. Hence, young dyslexic children may have deficits in both modalities, but older dyslexics may not show co-occurrence of visual and auditory impairments.

If deficient auditory rate processing can be considered a primary symptom of the lifelong condition, then distinctive features should also be detected in adults with dyslexia. For instance, Hari and Kiesilä (1996) employed trains of binaural clicks (four left-ear clicks followed by

four right-ear clicks), which produce an illusory perception of saltatory sound movement (from left to right) at short ISIs. In controls, this movement illusion disappeared at ISIs exceeding 90 to 120 ms. In dyslexics, who as a group were inferior to the controls on different measures of phonological processing, the illusion persisted up to ISIs of 250 to 500 ms. "Dyslexic adults thus seem to have a deficit in the processing of rapid sound sequences, which is also manifested in significant delays in their conscious auditory percepts" (p. 138).

Focusing on the Gestalt aspects of sound processing, Helenius, Uutela, and Hari (1999) studied auditory stream segregation³ in adults. Controls segregated a single sequence of alternating high- and low-pitched tones into two separate (one high and one low) streams at stimulus-onset asynchronies (SOA) of 130 ms and less, and dyslexics showed this same segregation effect already at SOAs around 210 ms. This was discussed as evidence for a prolonged auditory integration window in dyslexic individuals. Stream segregation correlated significantly with naming speed in dyslexics, indicating that slow access of phonological information is related to abnormal processing of rapid tone sequences.

Taken together, these auditory problems may be present and associated with phonological deficits in a significant proportion of dyslexic individuals. Findings provided by the adult literature on auditory perception seem to be less conflicting than those in the child population. An influence of experimental methods cannot be ruled out, however. Tasks administered to adults are often more challenging than those presented to children. The assumption that a rate processing deficit is causally related to phonological impairments in LLI has not received unequivocal support (Bishop, Bishop, et al., 1999; Marshall, Snowling, & Bailey, 2001). It remains to be seen whether the auditory dysfunction predicts phonological deficits or even LLI, or whether the perceptual problems are instead associated symptoms that are milder and less consistent in occurrence (Studdert-Kennedy & Mody, 1995; but see Denenberg, 1999, 2001). Prospective longitudinal studies including children who are at high familial risk for LLI may represent one avenue for revealing its causal relevance. This new line of evidence is introduced later in the chapter.

According to a recent version of the rate processing hypothesis, the deficit is not limited to the auditory modality.

³Rapid alternation of high and low tone sequences leads to the perception of two separate streams, that is, a high- and a low-pitched stream.

Similar constraints in coping with brief and rapidly occurring events have also been reported for other sensory and motor modalities in SLI and dyslexia. A multimodal or “pansensory” (Tallal, Miller, & Fitch, 1993, p. 27) rate processing dysfunction, although controversial, is assumed to have a particularly severe impact on the development of spoken and written language (Tallal, 1984; Tallal et al., 1993). Temporal sensitivity in the visual domain has also been investigated in the context of the magnocellular deficit hypothesis for dyslexia. This hypothesis is considered next.

Magnocellular Deficit

In the 1980s, Lovegrove and collaborators capitalized on the observation that poor readers may have visual problems, which could not solely be attributed to poor phonological awareness. Their experimental work has led to novel approaches stimulating research on visual processing in dyslexia (e.g., Lovegrove et al., 1982, 1986; Martin & Lovegrove, 1984, 1987, 1988; Slaghuis & Lovegrove, 1984, 1985, 1986). Lovegrove’s experiments were designed to test for visible persistence⁴ and contrast sensitivity differences between normal and dyslexic readers using grating stimuli. Findings indicate that children with dyslexia display longer-lasting visible persistence at low spatial frequencies (i.e., coarse gratings) and less sensitivity to gratings, particularly at low spatial frequencies, low contrasts, low luminances, and high temporal frequencies (i.e., fast-flickering gratings). Dyslexics often showed shorter visible persistence and slightly elevated contrast sensitivity at higher spatial frequencies than controls did (Lovegrove et al., 1982, 1986; Martin & Lovegrove, 1984, 1987, 1988; Slaghuis & Lovegrove, 1984, 1985, 1986). Problems in visual processing were observed in approximately 75% of a dyslexic group (Lovegrove et al., 1986; Slaghuis & Lovegrove, 1985). These digressions are present before children commence reading practice (Lovegrove

et al., 1986) and continue into adulthood (Slaghuis, Twell, & Kingston, 1996).

Psychophysical studies of various laboratories have confirmed Lovegrove’s findings (e.g., Borsting et al., 1996; Felmingham & Jakobson, 1995). Evidence is also provided by electrophysiological studies demonstrating that brain responses in dyslexic individuals were reduced or delayed for stimuli with low spatial and high temporal frequencies (e.g., Kubová, Kuba, Peregrin, & Nováková, 1995; Lehmkuhle, Garzia, Turner, Hash, & Baro, 1993; Livingstone, Rosen, Drislane, & Galaburda, 1991).

Lovegrove and colleagues discussed these results in terms of transient and sustained channels of the visual system. The transient system responds rapidly to low spatial and high temporal frequencies, low contrasts, and low luminances. The sustained system responds more slowly to medium and high spatial frequencies, low temporal frequencies, medium and high contrasts, and color differences (Maunsell & Van Essen, 1983; Merigan & Maunsell, 1993; Shapley, 1990). Transient visual processing is mainly mediated by large magnocells that constitute the magnocellular pathway between retina and cortex. Sustained processing, in turn, depends on the sensitivity of the smaller parvocells constituting the retinocortical parvocellular pathway (Merigan & Maunsell, 1993; Milner & Goodale, 1995). On the basis of primate and human visual studies, Breitmeyer and Ganz (1976) suggested that with each saccadic eye movement, transient/magnocellular channels normally inhibit sustained/parvocellular channels. As a consequence, the eidetic image of the previous fixation does not persist and does not mask the subsequent fixation. In dyslexic children, high persistence would cause masking and, ultimately, visual confusion during reading. Lovegrove et al. (1986) therefore proposed that the visual deficit in dyslexia reflects a failure of the transient system on sustained inhibition. A number of research groups, however, have found the magnocellular/transient system to be suppressed during saccades rather than the parvocellular/sustained system (Burr, Holt, Johnstone, & Ross, 1982; Burr, Morrone, & Ross, 1994).

Alternatively, Vidyasagar (2004) proposed that reading can be viewed as a serial search process. He draws from recent findings in monkeys and humans, pointing to an interaction of the dorsal and ventral stream of visual cortical information processing. In this model, the dorsal stream is dominated by magnocellular input controlling information flow into the ventral stream, which predominantly processes parvocellular input. In dyslexia, a deficit of the magnocellular/dorsal stream or a dysfunction at the level of

⁴“Visible persistence is defined as any continued visible response occurring after stimulus offset that is phenomenally indistinguishable from that occurring during the actual presence of the stimulus” (Lovegrove et al., 1982, p. 309). Duration of visible persistence has been typically assessed by displaying spatial frequency gratings sequentially in time (e.g., Slaghuis & Lovegrove, 1985). For example, participants are required to report detection of a blank field between the grating stimuli. Failure to detect the blank field indicates that the image of the first stimulus was still apparent at the onset of the second. Thus, the duration of the interstimulus interval at which the blank field becomes detectable can be regarded as a measure of the duration of visible persistence.

interaction between the two pathways may affect the spatiotemporal gating functions, which are necessary for reading. Such models will make significant progress when additional findings on neurocognitive mechanisms of visual processing emerge.

Several psychophysical and electrophysiological studies failed to confirm that reduced contrast sensitivity is associated with dyslexia (Gross-Glenn et al., 1995; Hayduk, Bruck, & Cavanagh, 1996; Johannes, Kussmaul, Münte, & Mangun, 1996; Victor, Conte, Burton, & Nass, 1993; Walther-Müller, 1995). Two factors are discussed in this context: (1) Only a subgroup of the dyslexic population exhibits abnormal visual magnocellular function, and (2) spatiotemporal contrast sensitivity tasks may not be sensitive enough for stimulating the magnocellular retinocortical stream. Experiments in monkey visual cortex indicate that motion stimuli are most selective for the magnocellular system (Newsome & Paré, 1988). Indeed, individuals with dyslexia were less sensitive than controls to moving stimuli both in psychophysical (Cornelissen, Richardson, Mason, Fowler, & Stein, 1995; Everatt, Bradshaw, & Hibbard, 1999; Slaghuis & Ryan, 1999; Talcott, Hansen, Assoku, & Stein, 2000; Witton et al., 1998) and brain-imaging (Demb, Boynton, & Heeger, 1997, 1998; Eden et al., 1996) paradigms. Furthermore, performance in pseudoword reading, which is a measure of phonological skills, was found to be correlated with the sensitivity of detecting visual coherent motion in both dyslexic and normally literate adults (Witton et al., 1998). In contrast, Cornelissen, Hansen, Hutton, Evangelinou, and Stein (1998) reported that children's letter errors were best explained by independent contributions from motion detection and phonological awareness. Similar evidence comes from a study of Talcott, Witton, et al. (2000) involving an unselected sample of 10-year-old children. After controlling for effects of intelligence and reading, measures of auditory and visual sensitivity were found to explain independent variance in phonological awareness (manipulating phonemes in spoken words) and orthographic ability (discriminating written real words from pseudohomophones; e.g., *rain* versus *rane*), respectively. Thus, auditory and visual magnocellular function may separately affect the ability to extract phonological and orthographic information during reading.

Unlike grating contrast-sensitivity measurements, which were dominated by the retinohthalamic pathway, motion detection critically involves more central functions of the magnocellular system (Stein, Talcott, & Walsh, 2000). Central functions are assumed to be closer to cognitive skills required for reading. Alternative mechanisms have

been put forward, by which a magnocellular/transient-system deficit could cause visual confusion during reading at higher levels of processing (Stein & Walsh, 1997). For instance, attentional deficits or destabilized binocular fixation may represent indices of such putative central dysfunction (Stein & Fowler, 1981, 1993; Stein, Richardson, & Fowler, 2000).

A recent unifying hypothesis maintains that the magnocellular dysfunction is not restricted to the visual pathways, but is generalized to all sensory modalities (auditory, visual, and tactile) as well as motor systems controlling fine-grained movements. The general deficit may lead to a variety of sensorimotor symptoms and, consequently, phonological impairments, depending on the most affected system (Stein, 2001). It is posited to evolve early in development of genetically predisposed individuals. The premise is that magnocells constitute a unique population arising from a separate developmental lineage with common surface antigens, heavy myelination, and rapid membrane dynamics, all of which contribute to their exquisite temporal resolution. However, these common characteristics may also render them, as a class, more vulnerable to immunological attack. Evidence for such pathophysiological mechanisms is suggested from genetic as well as neurobiological research in both dyslexia and SLI (see the following sections).

Neurobiological Approaches

SLI and dyslexia have long been assumed to have a neurodevelopmental origin. During the past decades there has been a growing interest in the neurobiological correlates of both conditions. In what follows, relevant findings from postmortem, neuroimaging, and electrophysiological studies are reviewed. Related animal data conclude the section on neurobiological approaches.

Postmortem Studies

Galaburda and colleagues have conducted a series of postmortem studies of diagnosed cases of dyslexia (Galaburda, Sherman, Rosen, Aboitiz, & Geschwind, 1985; Humphreys, Kaufmann, & Galaburda, 1990; Jenner, Rosen, & Galaburda, 1999), providing evidence of small areas of cortical dysgenesis. This includes small nests of abnormally placed neurons called ectopias and focally distorted cortical lamination or dysplasia. The dysgenesis varied in number and location from brain to brain and tended to involve the language-related perisylvian cortex. The observed dysgenesis

might reflect neuronal migration errors that may have occurred during fetal development.

The planum temporale in the left hemisphere has for long been suggested to be an important index of left hemispheric language lateralization. It is a triangular landmark situated on the supratemporal surface just posterior to the first Heschl's gyrus, inside the Sylvian fissure (see Figure 7.2). The left planum coincides with part of Wernicke's speech comprehension area (Galaburda, 1993; Shapleske, Rossell, Woodruff, & David, 1999). Postmortem observations of 200 adult brains (Geschwind & Levitsky, 1968; Wada, Clarke, & Hamm, 1975) revealed a dissymmetrically larger left planum temporale in 73.5% of the brains, whereas 10.5% showed a rightward asymmetry and 16% a symmetrically sized organization. Corresponding figures reported on 307 ordinary fetal or neonatal specimens were 55%, 16%, and 29% (Chi, Dooling, & Gilles, 1977; Wada et al., 1975). Galaburda et al. (1985) and Humphreys et al. (1990) found symmetrically sized planum temporale in the dyslexic brains due to an enlarged right hemisphere planum.

Another set of postmortem examinations was performed on thalamic structures, that is, the lateral geniculate nu-

cleus (LGN) of the visual pathway and the medial geniculate nucleus (MGN) of the auditory pathway. The magnocellular layers of the LGN were found to be more disorganized in dyslexic than in normal brains (Galaburda & Livingstone, 1993; Livingstone et al., 1991). Furthermore, dyslexic brains' magnocell bodies were 27% smaller and appeared more variable in size and shape. No differences were seen in the parvocellular lamination or the parvocell size of the LGN. In the same autopsy specimens, Galaburda, Menard, and Rosen (1994) reported smaller MGN neurons on the left side for the dyslexic brains specifically. These also exhibited a relative excess of small neurons and a relative paucity of large neurons on the left side as compared to control brains. The structural deviances found in the LGN of dyslexic brains may reflect slowness in the early segments of magnocellular channels, whereas the MGN differences may be related to auditory rate processing dysfunctions described in language-impaired children (Galaburda, Schrott, Sherman, Rosen, & Denenberg, 1996).

Galaburda's group has presented autopsy data on nine brains of individuals (six males and three females) with a history of dyslexia. Three of the male and one of the female patients were reported to have histories of delayed language acquisition (Galaburda et al., 1985; Humphreys et al., 1990). All dyslexic brains have displayed evidence of symmetric plana temporali (Galaburda, 1988, 1989; Humphreys et al., 1990). Neuronal ectopias and architectonic dysplasias were observed in all male cases and two of the females (Galaburda, 1993). Other cerebrocortical deviances in dyslexic autopsy specimens such as microgyria and cortical scars were less uniform than the pattern of dysgenesis (Galaburda, 1993). Overall, dyslexic female brains showed fewer and differently located microcortical malformations when compared to male brains (Humphreys et al., 1990). Histological differences in thalamic structures are limited to reports on five dyslexic brains versus five (Livingstone et al., 1991) or seven (Galaburda et al., 1994) control brains. Galaburda (1988, 1989, 1993; Galaburda et al., 1996) has hypothesized that dyslexia arises as a consequence of anomalous neural development, possibly resulting from brain injury during the prenatal period.

To complete the picture, two postmortem findings in SLI children should be briefly mentioned here. Landau, Goldstein, and Kleffner (1960) observed bilateral perisylvian cystic lesions with surrounding dysplasia and a severe retrograde degeneration in the MGN of a male brain. In a female autopsy specimen, Cohen, Campbell, and Yaghai (1989) found a dysplastic microgyrus in the left insular cortex and decreased asymmetry of the plana temporali.

Figure 7.2 Approximate location of perisylvian areas of the left hemisphere. Note that anatomical structure varies among individual brains. Adapted from *MRI Measurements of Broca's Area Predict Naming Speed*, by C. M. Leonard, et al., 2003, Proceedings of the Bangor Dyslexia Conference, available from <http://www.dyslexia.bangor.ac.uk/conferences.html>. Brain image from the Brain Biodiversity Bank of the National Museum of Health and Medicine, The Michigan State University, and the University of Wisconsin supported by the U.S. National Science Foundation, <http://www.brainmuseum.org>, <http://www.brains.rad.msu.edu>. Despite the robustness of most of the findings provided by Galaburda and collaborators, there are methodological issues complicating the interpretation of the results. For instance, many subjects with dyslexia had a history of comorbid disorders or prior head injuries (Galaburda et al., 1985; Humphreys et al., 1990), which would have prevented their participation in neuroimaging studies. Another concern may be seen in storage duration of postmortem brains. It is conceivable that the brains of dyslexic subjects have been stored for a longer period of time than those of the control subjects, putting them at higher risk of cell shrinkage. Also, the number of autopsy specimens examined so far is small. In postmortem studies, reliable identification of microanatomical deviances in general and the boundaries of the planum temporale in particular have often proved to be difficult (Kirch & Weinberger, 1986; Shapleske et al., 1999).

Structural Neuroimaging Studies

The irregularity with respect to the planum temporale has also been observed in vivo neuroimaging studies of perisylvian language regions. Authors employing magnetic resonance imaging (MRI) reported unusual asymmetry (i.e., Right hemisphere = Left hemisphere or right hemisphere > Left hemisphere) of the planum temporale in individuals with SLI (Gauger, Lombardino, & Leonard, 1997) or dyslexia (Flowers, 1993; Hynd, Semrud-Clikeman, Lorys, Novey, & Eliopoulos, 1990; Larsen, Høien, Lundberg, & Ødegaard, 1990). Larsen et al. found that 13 out of 19 dyslexic adolescents displayed symmetric plana as compared to only 5 out of 17 normal readers. All dyslexics exhibiting phonological problems showed absence of typical leftward asymmetry. This led the authors to propose that symmetrical plana temporali might be a possible neurobiological substrate for phonological processing impairment in dyslexia.

Measurements of the greater perisylvian region in the vicinity of the planum temporale have also yielded deviations in both SLI and dyslexia (see Figure 7.2). Plante, Swisher, Vance, and Rapcsak (1991) evaluated MRI scans of the broader perisylvian-language area in 16 boys with and without SLI. Seventy-five percent of the SLI children did not show the usual leftward asymmetry, and 25% of the controls showed atypical perisylvian configuration. Deviant asymmetry patterns were also observed more frequently in first-degree relatives of children with SLI, supporting the notion of a biological predisposition (Plante, 1991).

In SLI, Gauger et al. (1997) demonstrated greater rightward asymmetry of planum+, which includes both planum

temporale and planum parietale (i.e., the posterior, vertical part of the planum). Heiervang et al. (2000) found no changes in the lateralization of the planum+ in boys with dyslexia. Analyzing the planum parietale, they found that dyslexics were less likely to show the expected rightward asymmetry than controls.

Regarding anterior portions of the perisylvian region, SLI children showed a tendency toward atypical right-greater-than-left asymmetry of the pars triangularis, which coincides with parts of Broca's speech production area (Gauger et al., 1997). De Fosse et al. (2004) replicated observations of reversed asymmetry in anterior language cortex in boys with SLI. In a similar vein, adult male dyslexics demonstrated stronger right-hemisphere preponderance for Broca's region (Robichon, Levrier, Farnarier, & Habib, 2000).

The issue of perisylvian asymmetries is not conclusive, however. There have been other contradictory observations reported in both SLI and dyslexia. Some investigators have challenged the view of altered planum temporale asymmetry (Best & Demb, 1999; Heiervang et al., 2000; C. M. Leonard et al., 1993; Preis, Jäncke, Schittler, Huang, & Steinmetz, 1998; Robichon et al., 2000; Rumsey, Donohue, et al., 1997; Schultz et al., 1994). For instance, C. M. Leonard et al. found an exaggerated leftward asymmetry in the planum temporale in a group of compensated dyslexics compared to unaffected relatives and controls. Best and Demb observed similar asymmetries in planum temporale lateralization; however, this lateralization was reduced when the sulcal tissue was excluded from analysis. Criticism has also arisen with respect to planum parietale asymmetries (Gauger et al., 1997; C. M. Leonard et al., 1993; Preis et al., 1998; Rumsey, Donohue, et al., 1997). Eckert et al. (2003) have suggested a different anatomical basis in pars triangularis and the cerebellum. They found that measures of the right cerebellar anterior lobe and the left and right pars triangularis correctly classified a majority of the subjects (72% dyslexics and 88% controls). Several factors may contribute to these inconsistencies. For instance, variations in measurement techniques (such as defining the anatomical boundaries) as well as methodological and design flaws (such as small sample sizes, differences in diagnostic standards, and comorbidity) have been proposed (Heim & Keil, 2004).

As a promising new variable, parameters of white matter morphometry have been studied. Examining the microstructure of temporoparietal areas using diffusion tensor imaging, Klingberg et al. (2000) observed reduced integrity of white matter tied to the left hemisphere as a function of reading test performance. In a study by Herbert

et al. (2004), radiate white matter volume of SLI children was enlarged compared to controls. These findings have been interpreted as evidence for a general deficit in cerebral connectivity as an etiological factor contributing to developmental language disorders.

One suggestion proposed to explain the observed reduction in cerebral asymmetry in LLI is that it might be the result of anomalous interhemispheric pathways coursing through the corpus callosum to the perisylvian-language regions (Filipek, 1995). Based on animal models, Galaburda's group (Galaburda, Rosen, & Sherman, 1990; Rosen, Sherman, & Galaburda, 1989) has hypothesized that more symmetric brains have a stronger interhemispheric connectivity, which may be reflected by a larger size of the corpus callosum and vice versa. To date, there are only a few studies using MRI that compare the size of the corpus callosum in individuals with dyslexia and nondyslexic controls (Duara et al., 1991; Hynd et al., 1995; Larsen, Høien, & Ødegaard, 1992; Robichon & Habib, 1998; Rumsey et al., 1996; von Plessen et al., 2002). Results of these are not convergent. Some found an increase in the size of the corpus callosum in dyslexic individuals, especially in the posterior splenium (Duara et al., 1991; Rumsey et al., 1996) and its rostrally adjacent segment, the isthmus (Robichon & Habib, 1998; Rumsey et al., 1996), but others did not report this difference (Hynd et al., 1995; Larsen et al., 1992; von Plessen et al., 2002).

Mixed results characterize the literature on SLI as well. Gauger et al. (1997) measured normal total callosum size in children with SLI, although they tended to be less likely to show typical asymmetry patterns in perisylvian-language regions. Njiokiktjien, deSonneville, and Vaal (1994) found the corpus callosum to be larger in an LLI group exhibiting both familial SLI and dyslexia compared with non-familial cases. No differences for absolute corpus callosum size and its subareas were observed by Preis, Steinmetz, Knorr, and Jäncke (2000).

It is apparent that no consistent structural correlates have been associated with SLI or dyslexia using MRI techniques. Several factors possibly accounting for the inconsistent findings have been outlined earlier. Because the relationship of neurostructural deviances and behavior remains elusive, more insights can be expected from functional brain-imaging methods.

Functional Neuroimaging Studies

Regarding SLI, functional neuroimaging studies mainly presented single photon emission computer tomography (SPECT) data (Chiron et al., 1999; Denays et al., 1989; Tzourio, Heim, Zilbovicius, Gerard, & Mazoyer, 1994).

Their findings favor the hypothesis of deviant language lateralization in children with SLI. For instance, Denays et al. observed hypoperfusion in the inferior frontal convolution of the left hemisphere, encompassing Broca's area, in children with expressive impairments. In children having both production and comprehension deficits, hypoperfusion was evident in the left temporoparietal region as well as in the upper and middle areas of the right frontal cortex. Although Chiron et al. found similar hypoactivity in Broca's area of the expressive type, functional brain-imaging studies in SLI are sparse and need further corroboration.

The neuroimaging literature on dyslexia offers a number of functional investigations, using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). These techniques provide higher spatial resolution than SPECT. Most of the studies were conducted in adult individuals and primarily targeted mechanisms hypothesized to be compromised in dyslexia: phonological processing, auditory rate processing, and visual motion perception (magnocellular dysfunction).

Brain Activation during Phonological Tasks. Rumsey et al. (1992) were one of the first teams to perform PET scans on dyslexic adults. Male subjects participated in two tasks: a phonological awareness task, in which they were asked to press a button when two spoken words rhymed with each other, and a nonverbal task, in which they were required to push a button whenever a simple target tone in a sequence of others was detected. In controls, activation of left temporoparietal regions (angular/supramarginal gyrus) was specifically related to rhyme judgments. Dyslexics showed reduced blood flow in the left temporoparietal cortex during rhyming, but did not differ from controls in this area during rest or tone detection. The pattern of results was assumed to indicate a left temporoparietal dysfunction associated with phonological task demands in dyslexia.

S. E. Shaywitz et al. (1998) investigated dyslexic adults with fMRI using a set of hierarchically organized visual tasks intended to progressively increase demands on phonological analysis. The tasks required same-different judgments concerning line orientation (e.g., [VV]-[VV]), letter case (e.g., [bbBb]-[bbBb]), single-letter rhyme (e.g., [T]-[V]), pseudoword rhyme (e.g., [leat]-[jete]), and semantic category (e.g., [corn]-[rice]). On tasks making explicit demands on phonological processing (e.g., pseudoword rhyming), dyslexic adults in contrast to unimpaired readers showed a relative underengagement of left posterior regions (Wernicke's area, the angular gyrus, and striate cortex) coupled with a disproportionately elevated response in a

left anterior region (inferior frontal gyrus). This has been suggested to be a reflection of functional disruption in the posterior cortical systems engaged in phonological decoding and a compensatory reliance on Broca's area.

Similar brain imaging results using visual presentation of various phonological tasks have been reported by other researchers (Brunswick, McCrory, Price, Frith, & Frith, 1999; Paulesu et al., 1996; Rumsey, Nace, et al., 1997). These studies indicate that adults with dyslexia show typical or enhanced activity in left hemisphere frontal regions, but reduced or absent activity in left posterior areas. In contrast, McCrory, Frith, Brunswick, and Price (2000) observed right hemisphere differences during auditory verbal repetition. Dyslexic men demonstrated less hemodynamic activation than normal readers in the right superior temporal and right postcentral gyri. The mixed results seem to imply that the neural manifestation of phonological disruption in dyslexia is perhaps task specific. In fact, a current PET study by McCrory, Mechelli, Frith, and Price (2005) showed diminished metabolism in a left occipitotemporal area during word reading and picture naming.

Based on findings in adults, it is not possible to determine whether the digressions from typical cerebral response patterns in dyslexia reflect a fundamental deficit of phonological processing or are a compensation for poor reading in adulthood. There is hence growing interest in examining children and adolescents using fMRI. Temple et al. (2001) recorded data for 11-year-old dyslexic and normal-reading children during tasks of rhyming and matching visually presented letter pairs (e.g., *Do T and D rhyme?* and *Are P and P the same?* respectively). During (phonological) letter rhyming, activity in left frontal-lobe regions was evident in both groups, whereas activity in the left temporoparietal cortex was observed only in controls. During (orthographic) letter matching, normal readers demonstrated activity throughout the extrastriate visual cortex, whereas dyslexic readers showed reduced extrastriate responses. Thus, altered temporoparietal activation probed by rhyme letters in dyslexic children parallels prior findings in dyslexic adults, indicating a core phonological deficit. Moreover, childhood dyslexia may be characterized by impaired extrastriate activity thought to be important for orthographic processing.

In a study by Georgiewa et al. (1999), 14-year-old dyslexics showed reduced activation in Broca's area and in the left inferior temporal lobe during tasks that invoke substantial grapheme-phoneme conversions and phonological awareness. Neither the dyslexic nor the control group displayed temporoparietal activity, however. This finding is in contrast to what has been observed in younger children

(Temple et al., 2001) as well as in adult samples (see earlier remarks). The differences could be task related (covert behavioral response in the Georgiewa study versus overt response in the other studies), which has also been suggested by a more recent fMRI experiment of Georgiewa et al. (2002).

Studying a large sample of 144 individuals (7 to 18 years), B. A. Shaywitz et al. (2002) reported that dyslexic readers exhibited lesser activation than unimpaired readers in posterior brain regions (including parietotemporal sites and sites in the occipitotemporal area) and in the inferior frontal gyri during tasks relying on phonology. The reduced activity in anterior regions contrasted their earlier findings in adults (S. E. Shaywitz et al., 1998). However, a positive correlation between chronological age and bilateral activation in the inferior frontal gyri of dyslexic individuals led these researchers to suggest that frontal sites become increasingly incorporated with age in compensating for the posterior regions. Even though the notion of compensation is promising (S. E. Shaywitz et al., 2003), the influence of chronological age as an important factor needs to be examined in greater detail.

Brain Activation in Auditory Rate Processing. Although many imaging studies have explored the phonological hypothesis, only a few studies investigating the neural correlates of auditory rate processing in dyslexia have been carried out until recently. Using fMRI, Temple et al. (2000) employed nonspeech analogues of consonant-vowel-consonant stimuli with either brief (rapid) or temporally extended (slow) acoustic transitions differing in pitch in an active paradigm. Adult participants had to identify the higher pitched sound. Unimpaired readers displayed increased activity in the left prefrontal cortex in response to rapid relative to slow transitions, but dyslexic readers showed no differential activity. Further, magnitude of the differential response was inversely correlated with performance in rapid auditory processing, as measured by threshold needed for sequencing three 20-ms tones presented at different rates. Following these results, Temple and collaborators point to the possible role of left prefrontal regions as mediating rapid auditory processing.

Comparable evidence was obtained by Ruff, Cardebat, Marie, and Démonet (2002) using naturally spoken speech stimuli. Functional MRI scans of adult dyslexics and controls were compared during passive discrimination of syllable pairs selected from a /ma/-/na/ continuum. Speech rate was either normal or slowed down. Only in controls was discrimination of normally paced syllables associated with activation in a frontal-parietal network (Broca's area and

left supramarginal gyrus). The frontal component was less responsive to slowed speech in controls but predominantly activated in dyslexics. No modulation by speech rate was found in the parietal component, which has been considered pivotal for phoneme representations (Démonet, Fiez, Paulesu, Petersen, & Zatorre, 1996). The authors suggested that enhanced activation of Broca's area might reflect a neural correlate of improved performance on temporally extended syllables reported in children with SLI. Further, the left supramarginal gyrus was assumed to be compromised by a more severe deficit than speech rate dysfunction.

In a sample of healthy adults, Zaehle, Wüstenberg, Meyer, and Jäncke (2004) demonstrated shared neural networks (*viz.*, posterior perisylvian regions) for both verbal and nonverbal tasks. Such work needs to be conducted in both children and adults with LLI.

Brain Activation during Visual Motion Perception.

Several fMRI investigations provided evidence for a selective deficit in the magnocellular system in adults with dyslexia (e.g., Demb et al., 1997, 1998; Eden et al., 1996). Eden et al. measured cerebral activation while participants passively viewed either a coherently moving dot stimulus (magnocellular stimulus) or a stationary pattern (parvocellular stimulus). Moving stimuli were expected to elicit strong responses in area V5 (MT) that is located in an extrastriate region at the junction of the occipital and temporal lobes (Zeki, 1993). In unimpaired readers, the magnocellular stimulus activated V5/MT bilaterally, but it failed to activate this area in dyslexic readers. Parvocellular stimulus did not elicit any differences between the two groups.

Demb et al. (1997, 1998) examined brain signals in response to low-luminance moving gratings (magnocellular stimuli) as opposed to control stimuli "designed to stimulate multiple pathways" (1997, p. 13363). Dyslexic individuals showed reduced activity relative to controls both in primary visual cortex (V1) and several extrastriate regions (inter alia MT+) in response to moving gratings of various contrasts. Participants exhibiting stronger V1 and MT+ activity demonstrated better speed discrimination performance and tended to be faster readers.

Discrepancies in results might be attributable to differences in sample selection, stimuli, or procedures used for localizing visual brain areas. Whereas the phonological hypothesis of dyslexia has received valuable support from recent PET and fMRI research, hemodynamic studies on both visual magnocellular and auditory rate processing are limited, specifically in child populations.

Electrophysiological Studies

Functional MRI and PET provide excellent spatial resolution in examining brain processes believed to be compromised in LLI, and electroencephalography (EEG) and magnetoencephalography (MEG) allow us to investigate temporal processes in greater detail (see Figures 7.3a and 7.3b). Event-related potentials (ERPs)⁵ of the EEG are increasingly used in developmental and clinical research as they are noninvasive (like fMRI) and do not require overt responses by an individual (see Cheour, Leppänen, & Kraus, 2000; Leppänen & Lyytinen, 1997; Molfese et al., 2002; Nelson & Monk, 2001; Rockstroh et al., 1999). Their magnetic counterparts, termed *event-related fields* (ERFs), can be analyzed using methods increasing spatial resolution and estimating underlying sources. Therefore, MEG has the added advantage of high spatial resolution as compared to EEG and, in some instances, PET (Elbert, 1998).

Electroencephalography/Event-Related Potentials.

Visual ERPs have been frequently used to examine putative deficits in the magnocellular pathways in dyslexia. This work has demonstrated that dyslexics' ERP components were reduced or delayed for visual stimuli with low spatial and high temporal frequencies (e.g., Kubová et al., 1995; Lehmkuhle et al., 1993; Livingstone et al., 1991). Most recently, tasks involving moving stimuli, which are particularly sensitive to magnocellular deficits, have yielded supportive evidence in children (Scheuerpflug et al., 2004; Schulte-Körne, Bartling, Deimel, & Remschmidt, 2004).

A promising parameter suitable to investigate auditory processing in both normal samples and clinical conditions happens to be mismatch negativity (MMN). The mismatch response is elicited by a so-called passive oddball paradigm, in which infrequent acoustic (deviant) stimuli are interspersed in a series of frequently presented (standard) stimuli. The MMN likely reflects temporofrontal neural activity and usually peaks between 100 and 250 ms after stimulus onset. It is assumed to index a preattentive neuronal change-detection mechanism (Näätänen, 2001).

Mismatch studies using stop consonant-vowel syllables showed attenuated response in dyslexic and learning-impaired individuals compared to controls (Bradlow et al., 1999; Kraus et al., 1996; Schulte-Körne, Deimel, Bartling, & Remschmidt, 1998, 2001). Kujala et al. (2000) addressed

⁵Event-related potentials are characterized by precise time locking to a sensory stimulus (e.g., luminance change, tone, or mechanical tap) or internal event (e.g., preparation for a target stimulus). They can be detected by averaging single-trial responses.

Figure 7.3 (a) An EEG/ERP testing session showing a 9-month-old child seated on her mother's lap and being entertained by an experimenter during a passive auditory oddball paradigm. ERPs are recorded from 62 scalp sites (64 in adults) using the Geodesic Sensor Net (Electrical Geodesics, Inc., Eugene, Oregon). (b) An adult subject in a MEG laboratory. Pictured is a whole-head neuromagnetometer (MAGNES 2500, 4D Neuroimaging, San Diego, CA) inside a magnetically shielded chamber. The device houses 148 detection coils (magnetometers), forming a helmet-like array. It is sensitive to changes in magnetocortical activity, having temporal resolution in the range of milliseconds.

the issue of whether this mitigated mismatch response is due to a phonological processing deficit or a more general auditory impairment. They used two sets of stimuli, which were presented to adult dyslexics and normal readers: The test stimuli consisted of four 500-Hz tones with silent intertone intervals of either 200, 150, and 50 ms (standard pattern) or 200, 50, and 150 ms (deviant pattern); the control stimuli comprised 500-Hz tone pairs separated by either 150 ms (standard pair) or 50 ms (deviant pair). No group differences were found in the MMN amplitude to the temporal change in the control condition. In the test condition, for normal readers biphasic MMNs were elicited, but dyslexic readers showed only the second MMN. The biphasic MMN reflected a response to the two deviations in the test stimuli: a quick tone following the second sound, and a delayed tone following the third sound. The auditory system of the dyslexics seems to discriminate only the second deviation. Behavioral discrimination performance paralleled the mismatch findings. Kujala and collaborators inferred that dyslexic individuals have problems in processing auditory temporal information only when presented in a complex context, as in the case of the linguistic domain (i.e., phonemes in words), not otherwise. This study is one of the most informative concerning the two competing hy-

potheses. However, we need further work to clarify the relation between auditory rate processing and phonological skills, as other studies using simple nonverbal stimuli often showed normal MMN to duration changes in both SLI and dyslexia (Baldeweg, Richardson, Watkins, Foale, & Gruzelier, 1999; Korpilahti & Lang, 1994).

Magnetoencephalography/Event-Related Fields. Most MEG studies in dyslexia have been concerned with magnetic source imaging⁶ during performance of various reading tasks (Helenius, Salmelin, Service, & Connolly, 1999; Helenius, Tarkiainen, Cornelissen, Hansen, & Salmelin, 1999; Salmelin, Service, Kiesilä, Uutela, & Salonen, 1996; Simos, Breier, Fletcher, Bergman, & Papanicolaou, 2000; Simos, Breier, Fletcher, Foorman, et al., 2000). Overall, these studies support the findings of hemodynamic deviances in language-related brain sites in dyslexia (see section on Functional Neuroimaging Studies). For instance, Salmelin et al. found that print processing was associated with enhanced source activity in the inferior temporo-occipital border of the left hemisphere at about 180 ms following

⁶Neuronal source activity within a defined time window of ERFs is estimated and projected onto structural brain images.

stimulus onset in controls but not in dyslexic adults. Also, between 200 and 400 ms, controls showed activation in the left temporal region and dyslexic participants showed activation of the left inferior frontal cortex (approximately in Broca's area). This pattern may reflect posterior cortical anomaly and compensatory reliance on frontal lobe systems, which has been related to the phonological deficit discussed earlier. Differences in source activity in posterior brain sites have been detected in children with dyslexia during engagement in printed pseudo-word rhyme-matching and word-recognition tasks (Simos, Breier, Fletcher, Bergman, et al., 2000; Simos, Breier, Fletcher, Foorman, et al., 2000). Dyslexics displayed reduced activity in the left temporoparietal cortex following stimulus onset, coupled with a high density of source clusters in homologous right hemisphere regions as compared to normal developers.

Some recent MEG experiments in the auditory domain have examined early sensory components elicited by tones or speech sounds (e.g., Helenius, Salmelin, Richardson, Leinonen, & Lyytinen, 2002; Helenius, Salmelin, Service, et al., 2002; Nagarajan et al., 1999). In the context of the auditory rate processing hypothesis, Nagarajan et al. compared adult poor readers and controls on tone-sequence perception. Sequences of two brief sinusoidal tones differing in pitch were presented at each of three different ISIs, and participants were asked to press the appropriate buttons to indicate the correct order. Early ERF amplitudes (around 100 ms) for the second stimulus of a sequence were smaller in poor readers than in controls for ISIs of 100 or 200 ms, but not for the long ISI of 500 ms. This neuronal deviance was corroborated by a similar performance profile on tasks measuring perceptual interference between rapidly successive stimuli.

In the very same latency range, Heim, Eulitz, and Elbert (2003a, 2003b) reported asymmetrical localization of ERFs elicited by stop consonant-vowel syllables in controls. This asymmetry reflected a more anterior localization in the right hemisphere than in the left and was not present in dyslexic children or in dyslexic adults. Whereas there was no group difference in the left, dyslexics' sources in the right hemisphere were located posterior to those of controls. Right hemisphere anomaly also characterizes later time segments (150 to 300 ms) of the cortical response to syllables in language-impaired children (Heim, Eulitz, Keil, Rockstroh, & Elbert, 2003). These findings may reflect atypical organization of the primary auditory cortex and adjacent areas, in particular the planum temporale. As a consequence, other (right posterior) perisylvian

regions may become involved in auditory processing. Substituted regions, however, may not perform the task as efficiently as a normally developed planum temporale would.

Given the inconsistencies with functional neuroimaging studies, it is legitimate to ask whether SLI and dyslexia are necessarily limited to one or the other hemisphere. Various deficits making up the complex disorders might be associated with different neural bases. A complete picture, therefore, should include both high temporal and spatial resolution data as provided by a combined approach of electrocortical parameters and imaging techniques and, most important, theory-driven behavioral tasks (Heim & Keil, 2004).

Animal Studies

Given the neuroanatomic variance seen in the postmortem and neuroimaging studies described, it is posited that brain abnormalities hypothesized to be associated with LLI may occur quite early in life. As SLI may involve basic acoustic abilities that support language but are not speech specific, it is possible to examine such processes in an animal model (Clark, Rosen, Tallal, & Fitch, 2000; Fitch, Tallal, Brown, Galaburda, & Rosen, 1994). Studies of animals with induced cortical neuromigrational or genetic anomalies designed to mimic those found in LLI provide a converging framework to examine the existence of a common neurobiological mechanism, which acts developmentally to disrupt sensory processing systems (Fitch & Tallal, 2003). Research using animal models has improved our understanding of the ontogeny of these anomalies. Results obtained to date suggest that focal cellular anomalies such as ectopias and microgyria arise as a consequence of interference with critical periods of neuromigration, possibly resulting from focal ischemic damage (e.g., Dvorák, Feit, & Jurankova, 1978; Humphreys, Rosen, Press, Sherman, & Galaburda, 1991; Rosen, Sherman, Richman, Stone, & Galaburda, 1992; see Fitch & Tallal, 2003), originating in the prenatal period.

Studies using an animal model of induced neocortical microgyric lesions revealed that rats tested in a behavioral paradigm, similar to the infant tasks used by Benasich and colleagues (see section on Prospective Studies in Infants and Kindergartners), showed significant deficits in rapid auditory processing (Fitch et al., 1994). Such findings suggest that a common mechanism underlies specialization for rate processing in both humans and animals (Fitch & Tallal, 2003). Furthermore, these animals show anomalies in the thalamic medial geniculate nucleus or MGN (Herman, Galaburda, Fitch, Carter, & Rosen, 1997). Event-related

responses recorded from either surface electrodes or implanted electrodes (placed in the primary auditory cortex and in MGN) in mice with ectopias also document altered rapid auditory processing (Frenkel, Sherman, Bashan, Galaburda, & LoTurco, 2000). A strong and specific relation was shown between alterations in auditory ERPs and number of ectopias.

Several studies shed further light on the consequences of microgyric lesions in this animal model in the developing rat (Friedman, Peiffer, Clark, Benasich, & Fitch, 2004; Peiffer, Friedman, Rosen, & Fitch, 2004; Peiffer, Rosen, & Fitch, 2002). Specifically, it was demonstrated that developmental shifts in gap detection abilities are observable across early development, and that improvements in auditory acuity due to repeated testing can be observed even at the youngest ages (Friedman et al., 2004). In another study, juvenile rats with bilateral microgyria, but not their adult counterparts, exhibited impaired detection of short-duration silent gaps in white noise when compared to age-matched sham littermates (Peiffer et al., 2004). In adult rats, more temporally demanding acoustic discrimination tasks were required to elicit the deleterious effects of microgyria. These findings converge on data from humans with impairments in rapid auditory processing. In infancy and early childhood, an initial difficulty in gap detection is seen. Adults with a history of SLI or dyslexia may not show this deficit (McAnally & Stein, 1996; Protopapas, Ahissar, & Merzenich, 1997), nor is it consistent in older children (Bishop, Carlyon, Deeks, & Bishop, 1999). However, more demanding acoustic tasks (rapid, sequential, and brief stimuli) continue to elicit higher thresholds in dyslexic adults (e.g., Hari & Kiesilä, 1996).

Another current study indicates that the consequences of bilateral microgyria lesions (e.g., reorganization, alterations in thalamic morphology, and rapid auditory processing deficits) are surprisingly robust and do not appear to be ameliorated by passive acoustic stimulation across development (Peiffer et al., 2002).

Thus, the converging research cited here suggests that morphological abnormalities observed in the cortex and thalamic nuclei in both human and animal subjects may well play a part in inefficient rapid auditory processing (Herman et al., 1997; Jernigan, Hesselink, Sowell, & Tallal, 1991; Tallal, Jernigan, & Trauner, 1994). Further, there are clear differences elicited in the rat and mouse models as a function of age and perhaps environment, as has been proposed in humans (see Bishop & Snowling, 2004). Results of this kind support the utility of animal models in elucidating the potential mechanisms underlying finely

tuned auditory resolution, including the study of developmental changes in the auditory system (Fitch et al., 1994; see Fitch, Read, & Benasich, 2001).

Genetic Approaches

Over the past decades, evidence was collected in support of the hypothesis that SLI and dyslexia, or at least some subtypes of these conditions, may be hereditary. Initial reports of family aggregation derived from individual family case histories, and case-control family studies followed. Other research focused on examining the concordance of oral and written language impairments in twins as a means of looking at the rate of heritability. Findings of both family aggregation and twin studies have stimulated the quest for genes involved in the transmission of LLI.

Family Aggregation Studies

Both SLI and dyslexia cluster in families and in many cases co-occur in the same individuals (see section on Prevalence Estimates). Case studies capitalizing on family histories of language-impaired children showed that 24% to 63% of the children had at least one affected relative (Byrne, Willerman, & Ashmore, 1974; Gopnik & Crago, 1991; Hurst, Baraitser, Auger, Graham, & Norell, 1990; Ingram, 1959; Luchsinger, 1970; Robinson, 1987). The wide range in frequency rates might be due to differences in diagnostic standards and subject characteristics. Plante, Shenkman, and Clark (1996) compared direct testing versus questionnaire data in groups of parents of children with SLI and adult controls. Questionnaire results indicated that 38% of the parents having an affected child exhibited prior impairments in oral and/or written language skills. None of the controls reported such history. Corresponding SLI figures based on test battery scores were 63% and 17%. Gopnik and Crago tested 20 (out of 36) members of a three-generation family and found only seven to fall in the normal range of language development. Some of the affected members, however, would not be considered SLI by conventional diagnostic standards (see section on Definition: Specific Language Impairment). The phenotype or behavioral profile was quite broad, including virtually every aspect of language. Also, mental impairments, a history of psychiatric problems, or oral-motor dysfunctions have been documented (Gopnik, 1994; Vargha-Khadem, Watkins, Alcock, Fletcher, & Passingham, 1995).

Several investigations determined the prevalence of speech and language problems in the family members of individuals with SLI as compared to data from relatives of

controls with no speech or language disorder history. In many of these case-control studies, the affected individual (proband) was clinically identified, and information about the family was collected by questionnaires (Bishop & Edmundson, 1986; Neils & Aram, 1986; Rice et al., 1998; Tomblin, 1989). Overall, a robust effect of familiarity was suggested. Rates of impairments in families of SLI probands ranged from approximately 20% to 25% versus 3% to 7% in control families. Higher percentages were seen when researchers used a broader phenotype that encompassed language and learning problems (Tallal et al., 1989a; van der Lely & Stollwerck, 1996). Here, the incidence of SLI was on the order of 40% to 80% in proband families and 20% to 30% in control families.

More recently, Tallal et al. (2001) used direct testing in a case-control family design and found the rate of SLI for the first-degree relatives of probands (30%) to be significantly higher than for control families (7%). Affectance rates for fathers and mothers were approximately equal, whereas brothers showed about 3 times higher incidence than sisters did. In proband families, SLI occurred in 13% of offspring (excluding the proband) with neither parent affected, 40% of offspring with one parent affected, and 71% of offspring with both parents having SLI.

Evidence of familial aggregation in dyslexia has been reported in very early case studies. For instance, Stephenson (1907) described a three-generation family history of dyslexia affecting six individuals. In a classic study based on interview data from more than 100 families, Hallgren (1950) estimated the risk for first-degree relatives to be 41%. Similar estimates have been obtained by researchers using direct testing, with familial recurrence rates for siblings and parents ranging from 39% to 43% and 27% to 49%, respectively (Finucci, Guthrie, Childs, Abbey, & Childs, 1976; Gilger et al., 1991; Vogler, DeFries, & Decker, 1985). The Colorado Longitudinal Family Reading Study tested reading and cognitive abilities in 125 reading-disabled proband families and 125 matched controls. Manifest deficits were found in primary relatives of probands, providing indirect evidence for the familial nature of the disorder (DeFries, Singer, Foch, & Lewitter, 1978). Although the phenotype of dyslexia varied considerably across these investigations, recurrence rates demonstrate striking similarity. Further, siblings appear to be at greater risk for reading and spelling impairments when at least one parent is diagnosed (Gilger, Hanebuth, Smith, & Pennington, 1996; Wolff & Melngailis, 1994).

Taken together, there is a high probability for family members to have some type of SLI or dyslexia when one

other member is affected. Communalities of the two disorders in terms of psychological and neurobiological variables raise the question of etiological interrelationships. This issue has been addressed by a very recent case-control family study, using a battery of language, reading, and auditory rate processing tests (Flax et al., 2003). Approximately two-thirds of the SLI probands also met diagnostic criteria for reading disability. The occurrence rates of SLI (25%) and reading disability (23%) in their immediate and extended relatives were significantly elevated compared to rates for controls. Of particular importance, a high co-occurrence (46%) of the two conditions was also manifest in the same sample of relatives. Consistent with epidemiological research, gender differences were observed in proband families for both conditions. Specifically, male family members outbalanced females by a factor of 2.

Family aggregation studies provide information about the extent to which SLI and dyslexia run down generations. Because family members share environmental factors as well as genes, this approach cannot be used to assess the heritability of any given disorder. Twin studies offer one possibility to answer research questions related to the genetic transmission in a natural environment.

Twin Studies

Twin studies take advantage of the fact that monozygotic (MZ) twins are genetically identical, whereas dizygotic (DZ) twins share on average 50% of their genes. Consequently, MZ twins should be concordant for inherited traits roughly twice as often as DZ twins. In this vein, Tomblin and Buckwalter (1994) examined 82 pairs of twins that included at least one child having SLI (proband). Based on direct testing, concordance rate of SLI was 80% for MZ and 38% for DZ twins. Similar rates have been reported by B. A. Lewis and Thomson (1992) in twins suffering from a variety of speech, language, and learning difficulties. Here, concordance rates amounted to 86% and 48%, respectively. In addition, Bishop (1992) demonstrated an interesting interplay between environment and genetic endowment, both differentially contributing to past and present language ability. Work from the same laboratory (Bishop, North, & Donlan, 1995) showed higher concordance for males than females, exemplifying the often reported gender ratio for SLI.

Concordance rate differences have also been demonstrated for dyslexia. Zerbin-Rudin (1967) reviewed 51 cases, of whom at least one twin within a pair suffered from reading problems. Level of concordance was nearly 100% for MZ and 35% for DZ pairs. Recruiting 62 pairs

from a mother-of-twins club, Bakwin (1973) reported rates of 84% and 20% for MZ and DZ twins, respectively. Subsequent research demonstrated a somewhat lower but still significant concordance ratio (68% for MZ twins versus 38% for DZ twins), possibly as a result of avoiding methodological shortcomings pertaining to sample recruitment and diagnostic standards (see DeFries & Alarcón, 1996).

Other behavior genetic studies make use of correlational and multiple regression analyses to assess heritability of language/literacy ability in the normal and deficient range. Such methods are based on the assumption that oral and written language skills represent continuous traits being normally distributed in the population. Heritability in the normal range is evident when correlations between probands' and co-twins' test scores are significantly higher for MZ compared to DZ pairs. When probands are ascertained by extreme low test scores, co-twins' scores on the same test will regress toward the performance mean of an unselected population. To the degree that the disability is heritable, there should be greater regression in DZ co-twin scores. If heritability estimates for LLI twins exceed those for normal samples, this indicates that certain genes contribute to the linguistic variance observed among affected individuals, but not to the variance in the general population (DeFries & Fulker, 1985; LaBuda, DeFries, & Fulker, 1986).

In a current project, Viding et al. (2004) assessed the heritability of SLI in a large community sample ($n = 972$ pairs) of 4-year-old twins. Regression analyses indicated that language disability as indexed by a composite score is being substantially influenced by genes. Group heritability showed an increasing trend from 38% to 76% as a function of severity of impairment. Although more boys than girls were found to be impaired, no differences emerged in terms of genetic and environmental contributions.

Moderate but significant heritability has also been demonstrated for the normal range of language ability at 4 years, which has amounted to 39% (Colledge et al., 2002). More than 50% of the genetic influence on language performance was found to overlap with genetic influence on nonverbal cognitive skills. This overlap may be even more pronounced at later stages of development (see the discussion on interrelations between verbal and nonverbal abilities in the sections on "Definition").

The two studies in preschoolers suggest similar heritability estimates for milder language disability (38%) and language ability in the normal range (39%). When the most severe cases are considered, heritability for language disability exceeds the value for normal language ability by ap-

proximately a factor of 2. This raises the possibility that genes may be more important in causing severe language impairment than milder variants of the condition. It is also conceivable that additional genes contribute to the phenotype of language disability, but not to the variance in normal language skills.

A study by Bishop, Bishop, et al. (1999) focused on heritability estimates of phonological and auditory processing skills in children with SLI and normal developers. Correlations between proband and co-twin on auditory scores were equally high for MZ and DZ pairs, suggesting an interpretation in terms of shared environment rather than genes. Nonsignificant results of extreme score analyses were asserted as further evidence for this view. In contrast, substantial heritability was demonstrated for phonological skills in the normal as well as deficient range. Following these and additional findings, Bishop, Carlyon, and collaborators (1999) propose that auditory deficits are neither necessary nor sufficient for causing SLI, but nevertheless can affect severity of impairment in genetically predisposed individuals.

Within the scope of the Colorado Twin Reading Study, DeFries, Fulker, and LaBuda (1987) performed regression analyses on literacy skills in a sample of 64 MZ and 55 DZ pairs (8 to 18 years). Group heritability for a composite score indicated that about 30% of the cognitive profile in dyslexia is attributable to heritable factors. This value increased to nearly 60% when a larger sample of 223 MZ and 169 DZ twins was examined (Wadsworth, Olson, Pennington, & DeFries, 2000). Alarcón and DeFries (1997) extended their analyses to a normal group of Colorado twins and likewise found substantial genetic influence (66%) on literacy scores.⁷

Somewhat different findings emerged from the London Twin Study involving 13-year-old children (J. Stevenson, 1991; J. Stevenson, Graham, Fredman, & McLoughlin, 1987). Deficits in spelling appeared to be significantly heritable, whereas reading performance was best explained by shared environment. Considerable variations in reading instructions among the U.K. children have been put forth as one possibility to explain the disparity (Bishop, 2001).

Several twin studies provide evidence that some components of reading and spelling performance are under strong genetic influence (see Grigorenko, 2001; Schulte-Körne, 2001). The Colorado Study (Olson, Wise, Conners, Rack, & Fulker, 1989) reported heritability (about 46%) for a

⁷In a proband group, heritability for the very same measure was 82%.

phonological decoding measure with a strong genetic contribution to reading performance on the order of 90%. Orthographic skills were not heritable, however. Research including a larger sample showed that 56% of orthographic ability in the lower range could be accounted for by genes (Olson, Forsberg, & Wise, 1994). Data on phonological awareness scores add similar evidence. More recently, high heritability scores have been obtained for rapid automatized naming (58% to 65%). Its relationship with reading measures suggested that reading deficits covary genetically with impaired rapid naming (Davis et al., 2001).

Olson and Datta (2002) explored the association of reading skills and visual processing across the full range of reading ability. Generally, children with better word-reading performance tended to display higher visual contrast sensitivity. Proband-co-twin correlations of test scores indicated significant genetic influence on individual differences in reading, but not in contrast sensitivity. The authors claim that the modest shared variance between these measures should be attributed to environmental factors.

Bishop and colleagues (Bishop, 2001; Bishop, Adams, & Norbury, 2004) addressed the issue of a common basis of SLI and dyslexia. Heritability of reading disability was strikingly high in children having difficulty in repeating pseudowords, whereas those with intact pseudoword repetition performance did not show impact of genes. Thus, genetic factors are specifically relevant when literacy problems are severe and/or accompanied by oral language impairment.

In summary, the genetic basis of at least some proportion of LLI has been repeatedly demonstrated. A word of caution is in order, however. First, the mechanism of genetic transmission remains to be elucidated, as there is evidence for both major locus and polygenic inheritance (see L. B. Leonard, 1998; Pennington, 1995; Schulte-Körne, 2001). Second, estimates of genetic variance still face a substantial number of methodological issues. For instance, less stringent criteria in selection of research participants tend to lower heritability estimates. Whereas environmental factors may be of particular importance for milder language and literacy impairments (see earlier discussion), subtype classification may promote more homogeneous results in behavioral genetic studies (e.g., Castles, Datta, Gayán, & Olson, 1999).

Molecular-Genetic Studies

In both SLI and dyslexia, several methods have been pursued to identify genes predisposing to disorder. Linkage analysis (indirect DNA analysis) aims at locating a disease gene with respect to its chromosomal region. There are re-

gions of human DNA, so-called polymorphic markers, that vary substantially across individuals but do not affect the phenotype. The familial transmission of the marker allele is compared with the transmission of the trait phenotype. Their genetic loci are considered to be linked when they are inherited more frequently than expected by chance. This linkage does narrow down the search to genes that are close to the marker on the chromosome (see Pennington, 2001).

For linkage studies, either multiple family members from large pedigrees or a number of nuclear families (or sibling pairs) need to be compiled, based on an affected proband. As far as SLI is concerned, several genetic loci have been identified. The SLI Consortium (2002) found linkage sites on the long arms (q) of chromosomes 16 and 19 when the phenotype trait was defined by impaired phonological memory or poor expressive language, respectively. Bartlett et al. (2002) reported evidence for linkage between a region on chromosome 13q and susceptibility for SLI by use of an LLI phenotype.

The majority of families segregating SLI show complex patterns of inheritance. The KE family, a three-generation pedigree, represents one exception in that approximately half the members encounter severe disturbances in speech and language. All affected individuals, but none of the unaffected, carry a defective gene (FOXP2) located on chromosome 7q. This suggests an autosomal-dominant transmission of a monogenic trait (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998). To date, there is no evidence that language-impaired individuals unrelated to the KE family exhibit such mutation (Meaburn, Dale, Craig, & Plomin, 2002; Newbury et al., 2002). Recently, O'Brien, Zhang, Nishimura, Tomblin, and Murray (2003) documented significant associations of two loci in the vicinity of FOXP2 and a language-impaired phenotype.

Gene linkage investigations in dyslexia posit loci on chromosomes 1 to 3, 6, 15, and 18 (see Fisher & DeFries, 2002; Grigorenko, 2001; Schulte-Körne, 2001). As one of the first teams in the field, Smith, Kimberling, Pennington, and Lubs (1983) observed linkage between the centromeric region of chromosome 15 and reading disability in families with apparent autosomal dominant transmission. Addition of more multiplex families provided evidence for the genetic heterogeneity of the disorder (Smith, Kimberling, & Pennington, 1991): Linkages were spread to a more distal region on 15q as well as on a site of the short arm (p) of chromosome 6. Significant localizations on the long arm of chromosome 15 have also been reported by other researchers (e.g., Grigorenko et al., 1997; Schulte-Körne, Grimm, et al., 1998). Close to these re-

gions, Taipale et al. (2003) uncovered a candidate gene for developmental dyslexia.

One of the most consistent findings provides linkage of dyslexia-related phenotypes to loci on chromosome 6p, especially in the vicinity of the human leukocyte antigen (HLA) region (Cardon et al., 1994; Fisher et al., 1999; Gayán et al., 1999; Grigorenko et al., 1997; Smith et al., 1991). HLA belongs to the major histocompatibility complex, a cluster of genes essential to the immune system. Several autoimmune disorders (such as Type 1 diabetes and rheumatoid arthritis) have been localized to HLA. An association between autoimmune disease and dyslexia was originally proposed by Geschwind and Behan (1982). Some researchers detected unusual serum antibodies in mothers of dyslexic children (Behan, Behan, & Geschwind, 1985; Vincent et al., 2002), but reports of comorbidity in probands with dyslexia and their immediate relatives for autoimmune disorders remain controversial (e.g., Gilger et al., 1998; Hugdahl, Synnevag, & Satz, 1990). Nevertheless, Stein (2001) suggested a possible neural-immune interaction in that the development of surface antigens common to magnocells is probably regulated by major histocompatibility complex molecules. Maternal prenatal mechanisms might modify the offspring's immunological profile (Gilger et al., 1998), contributing to deficient development of magnocells. In line with this notion, Benasich (2002) found that infants with a positive family history of autoimmune disorders performed less well on rapid auditory processing and language tests than controls did. Conversely, families with a positive history for SLI tended to exhibit elevated rates of autoimmune disorders (Choudhury & Benasich, 2003). Thus far, however, SLI has not been linked to chromosome 6.

The current studies suggest a potential genetic component underlying at least a subset of individuals with LLI. There is no evidence for overlap between the gene linkages found in SLI and dyslexia. Consistency of the molecular genetic data is moderated by a variety of variables, including phenotype definition, sample size, and statistical methods used. Traditional linkage mapping is based on univariate analyses performed on several measures (e.g., phonological decoding, rapid automatized naming) constituting the phenotype. Usually, statistical adjustments are made for multiple tests. Marlow et al. (2003) demonstrated that the power to detect significant linkage increased when multivariate analysis was run. Therefore, one cannot infer that SLI and dyslexia are mediated by separate genetic mechanisms. None of the linkage results can be considered definite and detection of additional gene loci associated with oral and written language disturbances will likely emerge.

PROSPECTIVE STUDIES IN INFANTS AND KINDERGARTNERS

Substantial evidence continues to accrue that both SLI and dyslexia tend to occur across generations (see section on Genetic Approaches). Therefore, it is possible to study children who are at genetic risk as a function of family history for LLI even at a very early stage in their development. Prospective approaches using behavioral paradigms and electrocortical parameters may shed light on long-standing questions regarding etiology, developmental course, and pattern of deficits seen in these conditions. Moreover, interactive processes essential to normal and atypical language development may be delineated.

Specific Language Impairment

Given the extraordinary ability of very young infants to discriminate both speech and nonspeech acoustic input, differences in rapid auditory processing (RAP) thresholds should be detectable very early in infancy and could serve as a predictor of later language competence (Benasich & Read, 1999; Benasich & Tallal, 1996).

In infancy, RAP abilities are assessed in several different ways, including operantly conditioned head-turn procedures (Benasich & Tallal, 1996; Richardson, Leppänen, Leiwo, & Lyytinen, 2003; Trehub & Henderson, 1996), auditory-visual habituation and recognition memory tasks (AVH/RM; Benasich & Tallal, 1996), and EEG/ERPs (e.g., Benasich, Thomas, Choudhury, & Leppänen, 2002; Leppänen et al., 2002). Each paradigm capitalizes on systematic variations of the temporal properties inherent in the acoustic signal. In the head-turn procedure, an infant's orienting response to a target auditory signal is visually reinforced until a contingency develops and the child is able to reliably discriminate between target and nontarget sounds (see Figure 7.4). This task requires an infant to focus on the relevant auditory signal, learn the contingency, and sustain attention to the relevant auditory signal throughout the test session. AVH/RM paradigms are based on the well-known propensity of infants to differentially prefer novel as compared to familiar stimuli. Infants are first habituated to a complex auditory-visual stimulus, and auditory discrimination is assessed by the introduction of a novel auditory stimulus while keeping the visual component constant. A recovery of attention to the new auditory stimulus is taken as an indicator of auditory perceptual discrimination and recognition memory.

In a series of studies, Benasich and colleagues (Benasich & Tallal, 1996, 2002; Benasich et al., 2002; Choudhury &

Panel A

Panel B

Figure 7.4 Photographs of a 9-month-old infant attending to the experimenter performing a puppet show across the table from her (Panel A) and then correctly responding to a target sound (Panel B) in the test phase of a go/no go operant conditioning head-turn paradigm. Correct head-turns are contingently reinforced by activation of an electronic toy.

Benasich, 2003; Spitz, Tallal, Flax, & Benasich, 1997) examined two groups of infants: normal controls with no known family history of SLI (FH–) and infants born into families with a positive history of SLI (FH+). Group and individual differences in RAP abilities were examined using converging paradigms. In the initial study, infants were trained in a two-alternative forced choice procedure to discriminate two tone sequences that differed in pitch (100 and 100 Hz, or 100 and 300 Hz) with 75-ms duration tones and 500-ms intertone intervals (Benasich & Tallal, 1996). Once the tone-pair/direction contingency was acquired, the interval between the tones was dropped to 300 ms and then gradually decreased until the infant could no longer discriminate between the two tone sequences (the infant's RAP threshold). Infants first tested at 7.5 months of age were prospectively followed through 36 months (Benasich & Tallal, 2002; Benasich et al., 2002). At the initial visit, significant differences in RAP thresholds were ob-

served in FH+ infants as compared to FH– infants, with about 50% of the FH+ infants showing elevated thresholds (Benasich & Tallal, 1996).

Follow-up of this sample revealed that RAP performance in infancy was the best predictor of expressive and receptive language at 12, 16, and 24 months (Benasich & Tallal, 2002). Infant RAP threshold and being male together predicted 39% to 41% of the variance in 36-month language outcome. Discriminate function analyses permitted accurate classification to language-impaired versus nonimpaired groups at 36 months (using a criterion for impaired of at least 1 standard deviation below the mean of Stanford-Binet language subtests). Interestingly, no predictive relations were seen to nonverbal abilities such as motor or spatial skills.

These findings have been replicated in additional samples (see Benasich & Leevors, 2003). Detailed analysis of the data suggests that linguistic outcomes are related to

early RAP thresholds in both normally developing infants and infants at high familial risk for SLI.

Recently, Benasich's team (Benasich et al., 2005) showed that 6-month-old FH+ and FH- infants also differ in patterns of brain activation to virtually the same sounds presented in the behavioral RAP tasks. Moreover, amplitude and latency of a negative ERP component were reported to be inversely associated with expressive and receptive language abilities at 24 months of age. In a similar vein, Friedrich, Weber, and Friederici (2004) reported a delayed mismatch-like response to stop consonant-vowel syllables in German 2-month-old infants born into families with a history of SLI. Follow-up of these children as they begin to enter school is critically important.

The idea that individual variability in infant sensory processing is predictive of later language abilities fits well with findings from several other studies. For example, Trehub and Henderson's (1996) retrospective study revealed that children who performed above the median on auditory gap detection tasks in infancy had larger productive vocabularies, used longer, more complex sentences, and produced more irregular words at 16 to 29 months as compared with those who had scored below the median. In an ERP study conducted within 36 hours after birth, Molfese and Molfese (1985, 1997) reported that specific brain response patterns elicited by consonant-vowel syllables allow children to be sorted as to whether their verbal IQ is above or below the norm at 5 years of age.

It seems likely that early deficits in lower-level processing skills have their effect quite early on in development, when acoustic and phonological maps are being constructed (Benasich & Read, 1999). Slower, more effortful processing of acoustic information may contribute to an inability to extract the acoustic key features of a language and to map its unique phoneme distribution into the auditory cortex.

Developmental Dyslexia

The original and pioneering study in this area was done by Scarborough (1990, 1991), who followed a sample of 32 children, born into families with a history of dyslexia, from age 30 months through 8 years. At the end of grade 2, 65% of the at-risk children could be classified as reading disabled. Retrospective analyses of early language skills revealed that already at 30 months of age, those children who later became dyslexic produced shorter and less complex utterances as well as more errors in pronunciation. Tests of

receptive and expressive language at 36 and 42 months showed poorly developed vocabulary skills and continuing syntactic weakness. At age 60 months, these children were impaired in terms of letter-sound knowledge, object naming, and rhyming. They also had lower productive vocabularies, but the syntactic deficits reported for the younger age appeared reduced. The changing patterns of deficit reported were not observed in children from dyslexic families who became normal readers. Thus, dyslexics' deficits in early linguistic skills may not be exclusively phonological in nature and may manifest differently as a function of age.

Converging evidence is provided by other research teams. For instance, Lefly and Pennington (1996) followed 73 children at high risk for dyslexia and 57 low-risk controls from before entry to kindergarten through just before the start of first grade. In kindergarten, high-risk children were impaired in areas of letter knowledge, initial consonant detection, rhyme oddity, and rapid naming. Imminent to first grade, the two groups differed in terms of phonological awareness skills. Follow-up at the end of second grade revealed that 34% of the high-risk children had been diagnosed as reading disabled, compared with 6% of the controls (Pennington & Lefly, 2001). Even more striking was the finding that at-risk children, who were well within the normal reading range at the end of second grade, scored lower than controls on most measures of reading and spelling. However, children who went on to be dyslexic showed a broader phonological deficit encompassing both implicit (phonological retrieval and short-term memory) and explicit (phonological awareness) skills. Letter-name knowledge at age 5 continued to be a moderately good predictor of reading disability (Pennington & Lefly, 2001). In a similar vein, Elbro, Borström, and Petersen (1998) reported that Danish kindergartners with a history of parental dyslexia exhibited deficits on tests of morpheme deletion and articulation, but only those who later became dyslexic demonstrated collateral impairments in letter naming and a variety of phonological skills.

More recently, Gallagher, Frith, and Snowling (2000) documented literacy outcomes in children having a first-degree dyslexic relative and controls from nondyslexic families. When first seen at 45 months of age, at-risk children already showed signs of slower language development. At 6 years of age, 57% of the at-risk group was delayed in literacy development compared to 12% of the controls. Letter knowledge at 45 months was the strongest predictor of literacy level at age 6 years. A follow-up of this sample to age 8 years strongly suggests that children born into dyslexic families have an increased risk of literacy

problems even when classified as normal readers (Snowling, Gallagher, & Frith, 2003).

Following these findings, several researchers hold the view that dyslexia reflects a multifactorial trait consistent with the interaction of multiple genes and environmental factors, resulting in continuous phenotype variations (e.g., Pennington & Lefly, 2001; Snowling et al., 2003). "Arguably, when the level of risk reaches a certain threshold, the classic dyslexia profile emerges, but there are varying degrees of subclinical impairment, particularly in dyslexic families" (Snowling et al., 2003, p. 359).

Examination of developmental trajectories of prelinguistic infants differing as a function of familial risk for dyslexia is the focus of the collaborative Jyväskylä Longitudinal Study (see Lyytinen et al., 2004). Approximately 200 Finnish at-risk children and controls have been followed from birth through school age by using both behavioral and ERP paradigms. At the neural level, the earliest group differences have already been observed within a few days of birth: Whereas in controls, ERP responses to stop-consonant syllables were most evident over the left hemisphere, at-risk newborns showed greater activity over right temporal and parietal areas (Guttorm, Leppänen, Richardson, & Lyytinen, 2001; Guttorm, Leppänen, Tolvanen, & Lyytinen, 2003). The disparity was even more prominent when rate of stimulus presentation was slowed down (Leppänen, Pihko, Eklund, & Lyytinen, 1999).

Leppänen et al. (2002) further evaluated ERP components in 6-month-olds. Here, infants with a positive family history were found to exhibit less differential response to consonant-duration changes. Using a behavioral paradigm, Richardson and colleagues (Richardson, 1998; Richardson et al., 2003) demonstrated that at-risk infants of this age group required longer consonant duration to categorize speech sounds than controls did. This same divergence was observed in their dyslexic parents.

Maximal sentence length at age 2 years turned out to be the earliest language measure that differentiated the two groups. From age 3.5 years, at-risk children exhibited less well-developed phonological and naming skills and continued to be delayed when entering school and moving through the early grades. These early deficits were predictive of language and reading outcomes at school age (Lyytinen et al., 2001, 2004).

Overall, the earliest measures that highlight group differences are basic indices of speech processing in infancy. Significant predictive associations from infancy to school age have also emerged when early reading scores were used as dependent variables. Of particular interest is the finding that predictive relationships exist across the entire sample,

albeit higher in the at-risk group given its larger variance in predictor and dependent variables (Lyytinen et al., 2004).

As detailed here, a very large literature has accrued in the area of LLI and many studies have been conducted in older children already diagnosed with the disorder. Longitudinal studies have shown that more than 50% of children who meet diagnostic criteria for SLI subsequently or concurrently also meet the criteria for dyslexia, and many, but by no means all, dyslexic individuals show oral language deficits. Prospective studies extend research demonstrating differences between LLI and normal individuals to at-risk infants as a function of family history of language-based learning disorders. Such data indicate that identification and remediation must begin in the 1st years of life to prevent early impairments from exerting negative cascading effects on language, academic, and social skills.

REMEDIAL INTERVENTION

Research in animals and humans has demonstrated that central nervous system mechanisms can be modified by experience (see Buonomano & Merzenich, 1998; Elbert, Heim, & Rockstroh, 2001). As a consequence, neural plasticity has become an important research topic and theoretical framework for contemporary developmental psychopathology. For instance, animals raised in enriched environments or trained on motor tasks show relative increases of brain volume and number of synapses (Nelson, 1999). Experience-related changes in the sensory cortex are posited to occur as a consequence of heavy training schedules realized in behaviorally relevant settings (Elbert & Heim, 2001; Elbert et al., 2001). A promising approach to understand the neural underpinnings in SLI and dyslexia would thus be to assess the effect of training on affected individuals beyond the behavioral level. In fact, there has been a spurt in literature monitoring neurophysiological correlates of various intervention techniques.

As one point of departure, Merzenich and Tallal (Merzenich et al., 1996; Tallal et al., 1996) implemented a hierarchy of computer-based audiovisual training exercises aiming to ameliorate auditory rate processing and, ultimately, language skills. Considering both the mechanisms of neural plasticity and the finding of deficient processing of rapidly successive sounds, they submitted children with LLI to a daily training extended over 4 weeks. Rapid transitional speech and nonspeech stimuli were initially disambiguated by prolonging them in time and/or amplifying them. As training progressed and the children demonstrated

success, the modified acoustic stimuli were presented at rates that became closer and closer to those that occur in natural speech. Exercises resulted not only in improvements of auditory rate skills, but also in performance gains on phonological and language tests. Habib et al. (1999) found comparable evidence in children with dyslexia.

The effect of training on the brain processes underlying these changes was examined by Temple et al. (2003) using fMRI. They documented significant improvements in dyslexic children's oral language and reading performance following training. At the neural level, intervention effects were observed in brain regions typically associated with phonological processing (left temporoparietal cortex and left inferior frontal gyrus) as well as right hemisphere frontal and temporal regions and anterior cingulate gyrus.

Another potential method to parameterize the cortical effects of behavioral plasticity is the electrocortical mismatch response. Kujala et al. (2001) found enhanced MMN and faster reaction time to sound sequences following audiovisual training without linguistic material in a group of dyslexic children. Because these changes were accompanied by improvements in reading skills, the authors suggest that the disorder is at least partially based on a general auditory deficit.

In an intervention study with SLI children, Heim, Eulitz, Keil, et al. (2003) examined the magnetic counterpart of the MMN, the so-called mismatch field (MMF) evoked by stop consonant-vowel syllables. Children participated in multimodal training that included syllabic speaking, writing, and reading. The training of reading and writing followed a syllabic principle developed by Buschmann (Hofmann, 1998). Writing training had three major characteristics: First, the child said a word while writing it down (coarticulation); second, coarticulation was performed on a syllable-by-syllable basis (syllabic speaking); and third, before the child had learned coarticulation, he or she practiced syllabic speaking with flourishes of the writing arm while stepping sideways in the writing direction (flourishing exercise). Reading training was similar. Syllabic speaking was the same as during writing training, but the children coarticulated while drawing small inverted arches under the syllables. Improvements on various measures of literacy skills were found. Moreover, the syllabic training seemed to normalize neural response to phoneme processing: Before training, the SLI children displayed a stronger mismatch response in the right hemisphere than in the left, whereas their left hemispheric MMF was similar to that observed in controls. After training, groups did not differ in the magnitude of the right hemispheric MMF, leading to a comparable left-lateralized mismatch activity pattern.

Simos et al. (2002) used magnetic source imaging during a pseudoword reading task in children with dyslexia. They found a similar increase in the right hemisphere prior to intervention. Following training emphasizing phonology, there was a significant enhancement in the left superior temporal gyrus, although the peak activation was still delayed compared to the control children.

The MEG findings (Heim, Eulitz, Keil, et al., 2003; Simos et al., 2002) are in contrast to what has been observed using fMRI (Temple et al., 2003) with respect to the role of the right hemisphere during remediation. The inconsistencies could be modality related or task related. Another possibility is that there might be multiple subtypes of LLI with different underlying neuronal profiles: Heim, Eulitz, and Elbert (2002) contrasted the neuronal responses between two subgroups of dyslexic individuals. Group 1 displayed improved discrimination on temporally extended stop-consonant pairs, whereas group 2 did not show any difference. In terms of the neurophysiological correlates, only group 1 exhibited a right hemispheric MMF enhancement to prolonged syllables.

This brief survey indicates that remedial training in LLI can impact not only psychological and behavioral processes, but also neurophysiological parameters of cortical organization. Future studies need to address issues emanating from different subtypes of LLI, different modalities, different training methods, different tasks tapping various aspects of language/literacy skills, and also whether the resulting neural plasticity is a transient or permanent phenomenon. Nevertheless, findings on basic research represent an important avenue for the development and implementation of preventive interventions, which in turn may fertilize current theorizing.

FUTURE DIRECTIONS AND RECOMMENDATIONS

Despite almost 2 centuries of intense study and debate, there is surprisingly much that remains unspecified regarding the etiology, developmental trajectory, and mutability of childhood language disorders. Although substantial achievements in diagnostics, epidemiology, and remedial intervention of LLI have emerged in the face of technical advances in the behavioral and molecular neurosciences, considerable theoretical dissent still exists. An enduring question is whether phonological deficits observed in LLI are specific to linguistic systems or derive from constraints in basic mechanisms, encompassing attention, perception, memory, and/or motor processes. The research reviewed in

this chapter clearly indicates that both SLI and dyslexia reflect a heterogeneous group of disorders. Although the two conditions differ in several ways, there are also striking communalities in terms of behavior, epidemiology, heritability, functional neuroanatomy, and developmental precursors. However, the specific neurocognitive profile underlying the genesis and putative interaction of oral and written language difficulties is not as yet well understood. Thomas and Karmiloff-Smith (2002) recently claimed that the developmental process is pivotal for explaining the “end-state impairments” seen in such conditions. Similarly, Johnson (1997) put forth an interactive specialization approach, in which the process of organization of the interactions between brain areas across development is stressed. Cicchetti and Toth (1992) argued that developmental models are necessary to inform prevention and intervention efforts. Conversely, prevention and intervention trials in childhood disorders can contribute to our understanding of normal and abnormal developmental theory (Cicchetti & Hinshaw, 2002). Adopting a developmental psychopathology approach based on a multiple-levels-of-analysis perspective, we offer the following recommendations for future research:

1. Several studies failed to replicate the finding of an auditory rate processing deficit observed in SLI and dyslexia (see McArthur & Bishop, 2001). Negative results may arise from the use of less strict diagnostic standards (e.g., inclusion of children who scored only slightly below the norm in reading ability), advent of inappropriate tasks (e.g., very easy tasks produce ceiling effects), and the possibility that not all language/literacy impairments evolve from an auditory rate dysfunction (Fitch & Tallal, 2003). Recent work, however, suggests that subjects' age and maturation moderate auditory skills in LLI (Bishop & McArthur, 2004; Hautus, Setchell, Waldie, & Kirk, 2003; Wright & Zecker, 2004). Benasich and colleagues (Benasich & Tallal, 2002; Benasich et al., 2002, 2005) documented that rapid auditory processing abilities in infants differed as a function of family history for SLI and were predictive of later language outcome. This has been demonstrated by using behavioral as well as electrocortical parameters. Bishop and McArthur reported divergence of ERP and behavioral data in older individuals. Adolescents with SLI performed as well as controls in an auditory backward-masking task, yet all of the SLI participants showed aberrant ERP responses to the same stimuli presented in the behavioral paradigm. This may point to the possibility that older subjects have developed compensatory neural implementation to cope with behavioral deficits, and perhaps language/literacy skills. The use of convergent methodologies is hence highly recommended to detect (even subtle) sensory deficits and monitor developmental/maturational characteristics.
2. Continued research on basic deficits across modalities (auditory, visual, tactile, and motor) within the same LLI samples is required to evaluate the viability of a panmodality model (Stein, 2001; Tallal et al., 1993). Within this framework, several aspects should be addressed: (1) the impact of task difficulty or complexity, (2) the notion that a deficit in one or more modalities represents a subgroup-specific phenomenon, and (3) whether the putative cross-modal phenotype varies as a function of age.
3. The major competing hypotheses (phonological, auditory rate, and magnocellular deficit) for LLI should be studied in multiple case designs across different age groups to clarify outstanding issues regarding associative and causal relationships between the deficits (see also Ramus et al., 2003). Theory-driven behavioral tasks as well as exploitation of high-temporal and high-spatial resolution technologies (e.g., EEG and fMRI, respectively) may provide a complete picture.
4. Various techniques, such as EEG, MEG, fMRI, and PET, have been used to investigate the functional neuroanatomy of LLI. The findings, however, are not consistent in that many studies have observed a divergence from normal patterns related to the left hemisphere (e.g., Brunswick et al., 1999; S. E. Shaywitz et al., 1998; Temple et al., 2000), whereas others have reported a deviance related to the right hemisphere (e.g., Heim, Eulitz, & Elbert, 2003a, 2003b; Heim, Eulitz, Keil, et al., 2003; McCrory et al., 2000). As discussed earlier, the disparity might occur for a number of reasons, including the heterogeneity of disorders, task differences (e.g., reading versus auditory verbal repetition), and kind of measurement technique used (e.g., high-temporal MEG or high-spatial fMRI). It is conceivable that different subtypes of both SLI and dyslexia are associated with different neural substrates. Also, symptom diversity of the complex conditions may be reflected in a variety of neural bases. Systematic investigation of the aforementioned variables is therefore required to clarify these possibilities.
5. Another issue that needs to be examined carefully is whether the observed deviations in functional neuroanatomy vary in lower levels (phoneme or syllable) and higher (word or sentence) stages of linguistic processing (Hellige, 1993). There has been a burst of new

findings in the auditory literature indicating hemispheric differences with regard to rapid versus slower temporal processing (e.g., Poeppel et al., 2004; Zatorre & Belin, 2001). Poeppel and collaborators documented that auditory word/pseudoword judgments, categorical perception of consonant-vowel syllables, and direction discrimination of frequency-modulated tones differentially engage left and right auditory cortex. Such results suggest differential lateralization of phonetic versus prosodic processing for speech on the basis of differing spectral properties of the auditory input. However, neither the lateralization of phonemes (e.g., Tervaniemi et al., 2000) nor that of prosody (e.g., Baum & Dwivedi, 2003) has been completely understood yet. These issues might have implications in the understanding of the neural bases of LLI. One of the latest hypotheses proposed by Goswami et al. (2002) suggests that dyslexic children might in fact be impaired in rhythm detection, and this process of rhythm detection operates at a syllabic level. Further work is needed to understand the neural implications of this hypothesis.

6. Neurophysiological studies in child samples are necessary to investigate whether deviations from typical brain responses reflect a fundamental deficit or compensation for poor language and literacy skills in adulthood. There are a limited number of fMRI investigations exploring phonological and orthographic skills in dyslexic children, but auditory and visual rate processing needs to be examined in greater detail. As far as SLI is concerned, hemodynamic and electrophysiological studies are particularly scarce.
7. Another promising way to address the causality-compensatory issue is to assess the effect of training on neural processes. One goal that needs to be pursued for the advancement of both SLI and dyslexia research is to design clearly delimited intervention paradigms that tap specific deficits of the conditions or use the currently available techniques and clarify the effect of their specific components.
8. Early brain injury in rodents has been found to result in behavioral and morphological changes that vary as a function of age and experience and may produce altered psychophysical thresholds comparable to those observed in individuals with dyslexia and SLI (see section on Animal Studies). These variables have also been proposed to moderate basic sensory processing in humans (see Bishop & Snowling, 2004). Animal models are hence crucial for elucidating the potential substrates and mechanisms underlying acoustic processes in the course of development.
9. Prospective longitudinal studies beginning in early infancy are still few in number. Continued research in this area is needed to advance our understanding of developmental trajectories characterizing normal and atypical language. Here the use of different methodologies, such as theory-driven behavioral tasks, neurophysiological techniques, and molecular genetic approaches seems indispensable. For instance, ERP measurements can already be conducted in neonates and thus provide insights in early sensory processing. Data derived from at-risk infants compared to infants with a negative family history for LLI give us perhaps the most compelling evidence of the developmental impact of early sensory processing skills on language development and disorders under consideration.
10. Family-risk studies in dyslexia suggest that well-developed language skills help children to compensate for reading and spelling problems (Pennington & Lefly, 2001; Snowling et al., 2003). Literacy assessment should therefore always be accompanied by oral-language testing. Moreover, training of language skills needs to be considered an important building block of reading and spelling intervention programs.
11. There is a high risk of LLI in children whose immediate relatives themselves experienced language and/or literacy impairments (see section on Prospective Studies in Infants and Kindergartners). During early infancy, critical foundations of phonemic perception and later language are laid down. The potential for altering later outcome may be maximally effective during this early period. Development of age-appropriate training strategies based on prospective longitudinal research will be of great importance.
12. So far, linkage mapping and related analysis methods have revealed no overlap in gene loci for SLI and dyslexia (see section on Molecular-Genetic Studies). As outlined earlier in this chapter, statistical pitfalls (i.e., use of univariate testing) may have influenced such results. Further molecular-genetic investigations adopting a multivariate-analysis approach (Marlow et al., 2003) may open a new avenue to explore similarities or dissimilarities in SLI and dyslexia genotypes (see also Bishop & Snowling, 2004).

The overview presented here underscores the complexity of developmental language disorders and the critical importance of adopting a convergent methodological/developmental perspective. We have attempted to present an

integrated view of molecular, cellular, macroscopic, and behavioral evidence gleaned across disciplines that contribute to our current understanding of language disorders. It seems quite likely not only that the precursors of LLI can be seen very early in the 1st year of life, but also that language deficits persist, usually in subtle form, into later childhood, adolescence, and conceivably into adulthood. Therefore, the impact of developmental disorders of language on society is substantive. LLI has been shown to lead to reading and other academic achievement problems, an increased incidence of social and emotional problems, higher adjudication rates, and school dropout (see Snow et al., 1998; Tallal, 2004; Tallal & Benasich, 2002). The broad recommendations we delineate here represent an attempt to summarize the critical directions for basic research in this burgeoning field. With the advent of more sophisticated neuroimaging procedures and increasing use of converging methodologies and multiple levels of analysis, the opportunity for narrowing down the candidate causal mechanisms for such disorders is within our grasp. Future research may well lead to a better understanding of the neurobiological origins of language-based learning disabilities and the development of effective intervention techniques.

CONCLUSION 342

REFERENCES 343

Autism Spectrum Disorder is the term that is currently used to describe the broad range of pervasive developmental disorders. These disorders include Autistic Disorder, Asperger's Disorder (also referred to as Asperger's syndrome), Rett's Disorder, Childhood Disintegrative Disorder,

der, and Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS).

The Autism spectrum disorders involve impairments in reciprocal social interaction and communication and the presence of restricted, stereotyped, and repetitive interests and behaviors. Of these three symptom domains, impairments in social interaction are considered a primary feature of these disorders. These impairments include a lack of social and emotional reciprocity; atypical nonverbal behaviors such as atypical eye-to-eye gaze, facial expressions, body postures, and gestures to regulate social interaction;

The writing of this chapter was supported by the National Institute of Child Health and Human Development and the National Institute on Deafness and Communication Disorders (U19HD35465) and the National Institute of Mental Health (U54MH066399).

lack of interest and/or difficulty relating to others, particularly peers; and a failure to share enjoyment and interests with others. A great deal of heterogeneity exists among the Autism spectrum disorders in terms of the number and severity of symptoms across the three domains (social, communication, and stereotyped/restricted interests and behaviors) and in cognitive and adaptive functioning. Further, within each diagnostic category, impairments differ across individuals and, for any given individual, symptoms may change across the life span.

DIAGNOSIS, COURSE, AND PROGNOSIS

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*; American Psychiatric Association, 1994) and the *International Classification of Diseases*, 10th edition (*ICD-10*; World Health Organization, 1992) are two widely used systems for diagnosing Autism spectrum disorders. The specific criteria for each of the Autism spectrum disorders are described next.

Autistic Disorder

The diagnostic criteria for Autistic Disorder include at least six symptoms across three domains of functioning, with at least two symptoms in the area of social interaction, one in communication, and one in restricted interests and behaviors. Delays or abnormal functioning in at least one area—social interaction, language, symbolic or imaginative play—must be present before 3 years of age, and symptoms cannot be better accounted for by Rett's Disorder or Childhood Disintegrative Disorder (see following discussion). Individuals with Autism vary widely in symptom expression, cognitive level, and adaptive abilities. For a more detailed discussion, see the section on Symptom Presentation later in this chapter.

Asperger's Disorder

The characteristics that define Asperger's Disorder include intact formal language skills (e.g., vocabulary, grammar), with impairments in the social use of language and in nonverbal expression, social awkwardness, and idiosyncratic and consuming interests (Volkmar & Klin, 2001). Although motor clumsiness is not a defining feature of Asperger's Disorder, it is often observed (Volkmar & Klin, 2001). The *DSM-IV* diagnostic criteria for Asperger's Disorder include at least two symptoms in the domain of social interaction and one symptom in the domain

of restricted interests and behaviors. Further, individuals with Asperger's Disorder do not demonstrate clinically significant delays in general cognitive ability, self-help skills, and adaptive development. Differentiating Asperger's Disorder and high-functioning Autism is often difficult to do clinically, and the empirical validity of such a distinction has not yet been unequivocally established (Ozonoff & Griffith, 2000; Volkmar & Klin, 2001).

Asperger's Disorder was included as a separate diagnostic category only in the more recent revisions of the *DSM-IV* and *ICD-10* classification systems, and epidemiologic data on this subtype of Autism Spectrum Disorder are scarce. The first systematic epidemiologic study of Asperger's Disorder was conducted in Sweden and yielded a prevalence rate of 28.5 per 10,000 (Ehlers & Gillberg, 1993). In a review of epidemiologic surveys, Fombonne and Tidmarsh (2003) concluded that the number of children with Autism was 5 times that of children with Asperger's Disorder, on average, suggesting that the prevalence of Asperger's is approximately 2 per 10,000. The authors note that future studies should focus on slightly older children (ages 8 to 12 years) as Asperger's Disorder is often diagnosed much later than Autism.

Rett's Disorder

Rett's Disorder occurs in 1 in 10,000 to 15,000 individuals, has been reported only in females, and involves a progressive deterioration of functioning between 6 and 18 months of age. Children with Rett's Disorder follow an apparently normal prenatal and perinatal period of development, with typical, early psychomotor development and normal head circumference at birth. This period of fairly typical development is followed by a gradual loss of speech and purposeful hand use and the development of microcephaly, seizures, autistic features, difficulties in coordinating gait or trunk movements, and stereotypic hand movements. Interest in social engagement diminishes in the first few years following onset, but may reemerge later. Individuals with Rett's Disorder have severe impairment in language development, severe psychomotor retardation, and severe to profound mental retardation. It was discovered that some cases of Rett's Disorder are caused by mutations in the gene (*MECP2*) encoding X-linked methyl-CpG-binding protein 2 (Amir et al., 1999).

Childhood Disintegrative Disorder

Childhood Disintegrative Disorder (CDD), also termed Heller's syndrome, is characterized by a marked regression in several areas of functioning following typical develop-

ment in the first 2 years of life. Regression can occur any time after the first 2 years and before age 10, but onset typically occurs before 4 years of age. This regression typically includes a loss of previously acquired skills in at least two of the following areas: expressive or receptive language, social abilities or adaptive behavior, bowel or bladder control, play, and motor skills. Individuals with this disorder also demonstrate impairments in two of the three domains that characterize Autism: social interaction, communication, and restricted, repetitive behavior.

Approximately 1 in 3 to 5 children with Autism are also reported to show a regression in language and social skills following a period of ostensibly typical development, but this regression generally occurs prior to 24 months of age. These children are classified as having Autism rather than Childhood Disintegrative Disorder. For a more detailed discussion of developmental course in Autism, see later discussion.

CDD is very rare and much less common than Autistic Disorder (*DSM-IV*; American Psychiatric Association, 1994).

Pervasive Developmental Disorder Not Otherwise Specified

A diagnosis of PDD-NOS is given when there exist clinically significant impairments in social interaction and/or communication, or restricted interests and behaviors are present, but criteria for a specific Autism Spectrum Disorder are not met. This usually occurs in cases where symptoms are present but are too few in number to meet criteria for a specific diagnosis. Similar to the other diagnostic categories, a diagnosis of PDD-NOS includes individuals of varying symptom severity, cognitive ability, and level of adaptive skills.

Differential Diagnosis and Comorbidity

Accurate diagnosis is critical for obtaining proper treatment and the best possible outcome. Therefore, it is important to understand how Autism spectrum disorders differ from other commonly diagnosed disorders of childhood and which conditions are comorbid with Autism.

Differentiating among the Autism Spectrum Disorders

Although the *DSM-IV* defines Autistic Disorder, Asperger's Disorder, and PDD-NOS specified as separate disorders, children often receive different diagnoses within the Autism spectrum depending on the clinician and diagnostic instrument used to make the diagnosis. Although this can be confusing to parents and, in some cases, can impact

a family's eligibility for federal- and state-mandated intervention services, treatment recommendations are essentially the same across the spectrum (see section on interventions later in this chapter).

Mental Retardation

Estimates of the percentage of individuals with Autism who also have mental retardation range from 75% to 89% (Filipek et al., 1999; Fombonne, 1999; Steffenburg & Gillberg, 1986) to 40% to 71% (Baird et al., 2000; Chakrabarti & Fombonne, 2001). More recent (lower) estimates may reflect an increase in diagnoses of higher-functioning individuals and/or effective early intervention.

Although approximately 75% of children with Autism also have mental retardation, the two disorders can be distinguished based on differences in a number of areas. Studies that have compared children with Autism to children with mental retardation of similar intellectual ability have shown that children with Autism often exhibit an uneven cognitive profile that is different from children with mental retardation. This pattern consists of higher scores on measures of visual-spatial skills and auditory rote memory and lower scores on verbal comprehension (Happé, 1994; Lockyer & Rutter, 1970). In addition, a number of studies have identified differences between children with Autism and children with mental retardation in nonverbal communication skills, motor imitation, social cognition, play, and emotion recognition and expression (see Symptom Presentation section later in this chapter). Similarities include simple motor stereotypes, including self-injurious behaviors, which appear to be a function of mental age rather than diagnosis (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; Wing, 1978).

Due to the high comorbidity of Autism and mental retardation, the individual's developmental level and a thorough knowledge of typical developmental milestones is critical to making an accurate diagnosis.

Specific Language Impairment

All children with Autism have deficits in the communicative use of language (Lord & Paul, 1997; Tager-Flusberg, 1999; Wilkinson, 1998), and most have impairments as well in the formal aspects of language, such as vocabulary, complex syntax, and morphology, similar to those shown by children with specific language impairment (SLI)¹ (Bartak, Rutter, & Cox, 1975; Bishop, North, & Donlan, 1996;

¹SLI is a developmental language disorder that refers to below-average performance on standardized language tests in the absence of other disorders, such as mental retardation or hearing loss.

Dollaghan & Campbell, 1998; Gathercole & Baddeley, 1990; Tager-Flusberg & Cooper, 1999). Thus, Autism and SLI appear to be distinct disorders but highly comorbid. Research has compared the language profiles of children with Autism to those of children with SLI and found striking similarities. Children with Autism (ages 4 to 14 years) were given a language battery to assess phonological, lexical, and higher-order semantic and grammatical language skills (Kjelgaard & Tager-Flusberg, 2001). The sample was then divided into three groups based on their overall scores on the battery: normal, borderline, and impaired language. Children with impaired language demonstrated language profiles that were very similar to those previously observed in children with SLI, including better vocabulary relative to higher-order language abilities, poor performance on phonological processing (nonword repetition test), and difficulties in marking tense. This same group of researchers then examined the brain structure of children with Autism using magnetic resonance imaging (MRI), focusing specifically on the language regions of the cortex. Similar to children with SLI, the children with Autism showed larger right cortical regions relative to left regions, unlike controls, who showed larger left regions. These authors conclude that there is a subtype of children with Autism with the same neurocognitive phenotype as children with SLI. Genetic studies provide further clues to a shared genetic basis of these two disorders (see section on Etiology).

Nonverbal Learning Disability

Nonverbal learning disability (NLD) is characterized by lower nonverbal skills (i.e., visual-spatial, mathematics, handwriting) relative to verbal skills. Children with NLD also tend to be clumsy and exhibit social difficulties. Many children with Asperger's Disorder and some children with high-functioning Autism also meet criteria for NLD and may benefit from special educational services aimed at improving math and motor skills (Ozonoff, Dawson, & McPartland, 2002).

Tic Disorders

Many individuals with Autism exhibit stereotypic movements or vocalizations that are considered to be volitional and do not cause distress to the individual. Tics, however, refer to sudden, rapid, recurrent, stereotypical movements or vocalizations that cause marked distress to the individual and are generally believed to be involuntary. A study of 447 individuals with Autism spectrum disorders reported the presence of tics in more than 30% of the sample, with 4.3% meeting criteria for a specific tic disorder, Tourette's syndrome (Baron-Cohen, Scahill, Izaguirre, Hornsey, &

Robertson, 1999). An additional 2.2% were diagnosed with probable Tourette's syndrome, yielding a combined rate of 6.5%, which is greater than the general population risk. These results suggest an increased risk for tic disorders in individuals with Autism, although larger-scale epidemiological studies are needed.

Attention-Deficit/Hyperactivity Disorder

One of the most common initial misdiagnoses, particularly for children with high-functioning Autism and Asperger's Disorder, is Attention-Deficit/Hyperactivity Disorder (ADHD; Ozonoff et al., 2002). Children with ADHD show difficulties sustaining attention and organizing tasks, are easily distracted, often do not seem to listen when spoken to, exhibit an excessive activity level, interrupt others, and talk excessively. Many children with Autism and Asperger's Disorder exhibit these same symptoms, but for very different reasons. For instance, due to the significant social and executive function deficits in Autism, these children may not seem to be listening when spoken to and may interrupt others, talk excessively, and show difficulty in organizing tasks and following through on assignments. Key distinguishing features of Asperger's Disorder are profound difficulties in social interaction and the presence of preoccupations and restricted range of interests.

Obsessive-Compulsive Disorder

Children with Autism often exhibit an insistence on routines and rituals and a high need for order, which may be confused with Obsessive-Compulsive Disorder (OCD; Ozonoff et al., 2002). Most children with OCD experience their behavior as intrusive and odd and wish that they could stop performing the behaviors. They also experience anxiety that is alleviated by engaging in the behaviors. In contrast, children with Autism have little insight into the nature of their repetitive and ritualistic behaviors, do not realize that the behaviors may be considered odd, and do not try to stop engaging in them. In addition, the need for routine and order in Autism is only one in a constellation of symptoms that characterize the disorder. In some cases, an individual may suffer from both Autism and OCD. Comorbid diagnosis of Autism Spectrum Disorder and OCD ranges from 1.5% to 29% (Lainhart, 1999). In such cases, treatment should address both disorders.

Other Anxiety Disorders

Symptoms of anxiety are frequently observed in children across the Autism spectrum, making it difficult to determine whether these symptoms represent a truly separate disorder. Nevertheless, Lainhart (1999) estimated a 7% to

84% comorbid rate of anxiety disorders in individuals with Autism, with Generalized Anxiety Disorder, agoraphobia, separation anxiety, and simple phobia being the most common. Symptoms of anxiety can often be ameliorated by medication and/or appropriate behavioral interventions (see section on interventions later in this chapter).

Depression

Depression is commonly comorbid with Autism, occurring at rates ranging from 4% to 58% (Lainhart, 1999). Although symptoms of depression occur most frequently in adolescents and adults with Asperger's Disorder or PDD-NOS, they can occur in children (Ghaziuddin & Greden, 1998; Wozniak et al., 1997). Primary symptoms are not always related to mood and may include increased agitation, aggression, self-injurious behavior, increased engagement in compulsive and repetitive behaviors, social withdrawal, changes in sleep and appetite, and general deterioration in functioning (Howlin, 1997; Lainhart & Folstein, 1994). Major Depression in individuals with Autism is often ameliorated by antidepressant therapy (Lainhart & Folstein, 1994).

Seizure Disorders

Individuals with Autism are at increased risk for developing seizure disorders, with prevalence rates ranging from 5% to 39% (Ballaban-Gil & Tuchman, 2000; Tidmarsh & Volkmar, 2003) and age of onset either before 3 years of age or, more frequently, during puberty (11 to 14 years; Gillberg & Steffenburg, 1987; Goode, Rutter, & Howlin, 1994; Rutter, 1970; Volkmar & Nelson, 1990). Seizure disorders are more common in very low-functioning individuals (i.e., IQ of less than 50) and in females (Rutter, 1984; Volkmar & Nelson, 1990). In addition, epileptiform abnormalities without evidence of clinical seizures are also common (one study reported 21% of 392 children) in Autism (Tuchman & Rapin, 1997).

Early Identification

Some parents of children with Autism report being concerned about their child's development since birth, and, by 18 months, most parents raise concerns with their primary health care provider (Howlin & Asgharian, 1999; Rogers, 2001; Siegel, Pilner, Eschler, & Elliot, 1988). However, the age at which a diagnosis is confirmed tends to be much older. In a survey of 770 parents of children with Autism and Asperger's Disorder, the *average* age at which a formal diagnosis was confirmed was 5.5 years for Autism and 11

years for Asperger's Disorder (Howlin & Asgharian, 1999). Refining methods of early identification and diagnosis allows for early intervention and better outcomes for young children with these disorders.

Reliability and Stability of Early Diagnosis

Research indicates that symptoms of Autism are often present during infancy and that Autism spectrum disorders can be detected as early as 18 months of age and reliably diagnosed by 20 to 24 months (Baron-Cohen et al., 1996; Rogers, 2001). Further, there is now evidence that a diagnosis of Autism at age 2 remains stable over time. For instance, Lord (1995) found that 14 of 16 children receiving a clinical diagnosis of Autism at age 2 received an independent clinical diagnosis of Autism at age 3. Baron-Cohen et al. reported that 10 out of 10 children diagnosed with Autism at 18 to 20 months retained the diagnosis at 3.5 years. W. L. Stone et al. (1999) showed that 96% of the children in their study retained a diagnosis of Autism or PDD-NOS from age 2 to 3. Others have shown that diagnosis of Autism spectrum disorders in children under 3 years of age is reliable across clinicians, although less so when distinguishing Autism from PDD-NOS (W. L. Stone et al., 1999; Volkmar, Szatmari, & Sparrow, 1993).

Early Symptoms

Previous studies have identified a number of characteristics that distinguish preschool and early elementary school-age children with Autism from those with developmental delay. These include impairments in joint attention, imitation, symbolic play, and responses to emotion (e.g., Charman & Baron-Cohen, 1997; Charman et al., 1998; G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; G. Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998; Mundy, Sigman, Ungerer, & Sherman, 1986; W. L. Stone, Ousley, & Littleford, 1997; W. L. Stone et al., 1999). Relatively few controlled studies, however, have examined how children with Autism below age 3 differ from children with related disabilities, such as developmental delays, and most of these have relied on observations made from home videotapes (e.g., Baranek, 1999; Osterling, Dawson, & Munson, 2002). Charman et al. (1998) found that 20-month-olds with Autism were more impaired in joint attention, responses to another's distress, pretend play, and imitation, compared to those with language delay. Other studies found that 24-month-olds with Autism performed fewer joint attention gestures, including pointing and showing, and had more impaired language and imitation skills than typically developing and language impaired children (Lord & Paul, 1997; W. L. Stone et al., 1997).

Retrospective studies of home videotapes have been an especially fruitful area of research. Using this method, investigators have been able to observe the early social, language, motor, and play behaviors of infants who later receive a diagnosis on the Autism spectrum and to examine developmental differences between infants with Autism and typically developing infants (Mars, Mauk, & Dowrick, 1998; Osterling & Dawson, 1994) and infants with mental retardation (Baranek, 1999; Osterling & Dawson, 1999). In one such study, Osterling and Dawson (1994) examined videotapes of 1st birthday parties and demonstrated that 1-year-olds later diagnosed with Autism could be distinguished from 1-year-old typically developing infants. How often a child looked at the face of another person (gaze) correctly classified the greatest number of children (77%). When gaze was combined with the behaviors of showing, pointing, and orienting to name (i.e., social orienting), 91% of the infants with typical development and with Autism were correctly classified. These results were replicated by Mars et al., who used blind scoring to evaluate home videotapes of 1st birthday parties of 25 infants later diagnosed with Autism and 25 typically developing infants. Again, the variable "looks at faces" was found to be a powerful discriminator between the two groups, as well as joint attention (e.g., pointing) behaviors.

A subsequent home videotape study compared 1-year-olds later diagnosed with an Autism Spectrum Disorder (ASD) with 1-year-olds later diagnosed with mental retardation and 1-year-olds with typical development. This study showed that 1-year-olds with ASD could be distinguished not only from typical 1-year-olds, but also from 1-year-olds with mental retardation (Osterling et al., 2002). This is important due to the high comorbidity of Autism and mental retardation. In this study, the infants with ASD were less likely to look at others and to orient to their name than were infants with mental retardation. Joint attention behaviors, however, did not distinguish between ASD and developmental delay at 1 year of age, suggesting that other behaviors related to attending to people and other's speech might be important in distinguishing ASD from developmental delay at very young ages. In yet another home videotape study, a failure to orient to name was the best discriminator between 8- to 10-month-olds with ASD versus typical development (Werner, Dawson, Osterling, & Dinno, 2000). Again, joint attention did not distinguish the two groups at this young age.

Screening Instruments

A number of promising early screening methods have been developed to detect symptoms of Autism in infants and tod-

dlers, including the Checklist for Autism in Toddlers (CHAT; Baron-Cohen, Allen, & Gillberg, 1992), the Modified Checklist for Autism in Toddlers (M-CHAT; Robins, Fein, Barton, & Green, 2001), the Pervasive Developmental Disorders Screening Tests (PDDST; Siegel & Hayer, 1999), and the Screening Tool for Autism in Two Year Olds (STAT; W. L. Stone, Coonrod, & Ousley, 2000). However, none of these instruments are currently in widespread use. The CHAT, a parent report and behavioral observation measure, has been shown to have high specificity (98%) but low sensitivity (38%), suggesting that it is not adequate for screening in public health settings (Baird et al., 2000). More promising results have been shown for the M-CHAT, a parent report measure, with a specificity of 95% and a sensitivity of 97% (Robins et al., 2001). The PDDST differs from the CHAT and the M-CHAT in that it offers different versions for primary care clinics, developmental clinics, and Autism specialty clinics. The primary care version yielded a sensitivity of 85% and specificity of 71% (Siegel & Hayer, 1999). The STAT is still under development but has been shown to discriminate well between children with Autism and other developmental disorders in a small sample of 2-year-olds (W. L. Stone et al., 2000).

It is likely that screening methods currently under development will continue to need refinement. This refinement will depend on research aimed at identifying early emerging behaviors that can distinguish very young children with Autism from those with related disabilities, such as developmental delay. Behaviors such as joint attention, gestures, verbal language, and pretend play may have limited utility in distinguishing infants and toddlers with Autism from those with developmental delay as these behaviors are not normally present until 1 to 2 years of age; 18- to 24-month-old toddlers with significant developmental delay would not be expected to show these behaviors.

Developmental Course

There are generally two patterns of symptom development in Autism. The most common course involves the emergence of symptoms in the 1st year of life. In roughly a third of cases, however, there is a regression in skills following a period of fairly typical development.

Early Onset

Symptoms of Autism typically emerge early, within the first 12 months of life. This pattern of symptom development is referred to as early-onset Autism. Both parent report (Lord, 1995) and home videotape studies (Baranek, 1999; Osterling & Dawson, 1994; Werner et al., 2000;

Werner, Dawson, & Munson, 2001) have confirmed that for many children with Autism, symptoms may emerge as early as 8 months of age.

Regression

Symptoms of Autism may also appear after a period of fairly typical development, with a regression or loss of previously acquired skills generally occurring prior to 24 months of age. This pattern of symptom emergence in Autism has been estimated to occur in 20% to 47% of cases (e.g., Davidovitch, Glick, Holtzman, Tirosch, & Safir, 2000; Kurita, 1985; Lord, 1995; B. A. Taylor et al., 2002), with typical age of onset ranging from 16 months (B. J. Williams & Ozonoff, 2001) to 24 months (Davidovitch et al., 2000). Primarily, there is a loss of language skills, although losses can occur in social interest and responsiveness, nonverbal communication, cognitive ability, and self-help/adaptive behavior. Osterling and Dawson (1999) examined home videotapes of children with reported regression and found that, indeed, these children displayed typical social and communication behaviors at 1 year of age. However, using retrospective parent report, two other studies have shown that approximately 50% of the children who were reported to have lost skills after 1 year of age actually showed a delay in skills prior to the reported regression (Werner et al., 2001; B. J. Williams & Ozonoff, 2001). Werner and colleagues found that children with versus without a history of early regression did not differ in language, cognitive, or symptom outcome at age 3 to 4 years (Werner, Dawson, Munson, & Osterling, in press).

Autism across the Life Span

Although Autism is considered to be a lifelong disorder, the specific constellation of symptoms and the severity of those symptoms tend to fluctuate across development (Lord, 1997). One study reported improvements from age 5 in social and communication skills and in repetitive behaviors in a sample of 38 adolescents and young adults, with 13% of the sample no longer meeting criteria for Autism (Piven, Harper, Palmer, & Arndt, 1996).

With such changing patterns and severity of symptoms, both current and historical reports of symptoms are often required to make an accurate diagnosis and for inclusion in genetic studies of Autism. The Autism Diagnostic Interview-Revised (Le Couteur, Lord, & Rutter, 2003; Lord, Rutter, & Le Couteur, 1994) is a standardized, semistructured parent interview that provides both a current and a lifetime diagnosis for individuals with a mental age of 18 months or

greater. However, it relies on retrospective parent report and should therefore be combined with other sources of information, such as behavioral observation, in making a diagnosis. One such behavioral measure that is widely used is the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000; Lord, Rutter, DiLavore, & Risi, 1999; Lord, Rutter, Goode, & Heemsbergen, 1989), designed to assess individuals at varying stages of development and language level, from nonverbal children to high-functioning adults (there are four modules in all). The ADOS is a standardized, semistructured play interaction that provides opportunities for reciprocal social interaction, communication, and imaginative play and can be used across a wide range of chronological and mental ages (normative data exist for ages ranging from 15 months to 40 years).

Prognosis

Although the diagnosis of Autism tends to be quite stable into adolescence and adulthood, outcome is more varied. For as many as 75% of individuals with Autism, outcome tends to be poor. However, fair to good outcomes (i.e., adequate functioning in social, work, and school domains) are observed in at least 25% of individuals (Gillberg & Steffenburg, 1987; Nordin & Gillberg, 1998; Sigman & Norman, 1999). A more recent study that followed children with Autism from age 2 to age 9 found that as many as 40% obtained good outcomes based on language and cognitive scores (W. L. Stone, Turner, Pozdol, & Smoski, 2003). Although outcome is typically best for individuals with normal to near-normal intelligence, it is still lower than expected based on general intellectual ability. For instance, many individuals with Autism who have normal intelligence nevertheless require supervised living arrangements, are employed in low-level jobs, and do not develop friendships or marry (Tsatsanis, 2003). Compared to earlier studies (i.e., prior to 1980), however, there is evidence of better outcome in Autism in more recent years (Howlin & Goode, 1998). Improved outcome is likely related to availability of early and appropriate interventions.

Predictors of Outcome

Identifying specific factors that predict outcome in Autism is of critical importance for both researchers and clinicians and can lead to improved, targeted early interventions. IQ above 50 and language (specifically, meaningful speech by 5 to 6 years of age) remain the strongest predictors of positive outcomes for these children (Bartak & Rutter, 1976; Gillberg, 1991; Gillberg & Steffenburg, 1987; Lincoln, Courchesne, Kilman, Elmasian, & Allen,

1988; Lockyer & Rutter, 1970). Early language ability has been shown to predict both academic achievement and social competence (Howlin, Mawhood, & Rutter, 2000; Venter, Lord, & Schopler, 1992). In addition, a number of studies have indicated that early, intensive behavioral intervention is associated with higher IQ scores, a greater likelihood of developing language, and an increased chance of being placed in a regular education classroom (G. Dawson & Osterling, 1997; Lord & Schopler, 1989; Lovaas, 1987; McEachin, Smith, & Lovaas, 1993; Sigman & Ruskin, 1999).

Other predictors of language and social outcome include total speech and language therapy received, early expressive language ability, imitation and joint attention abilities, social interaction and shared affect, toy play, and age of diagnosis, with earlier diagnoses relating to poorer outcomes (Rogers & Hepburn, 2003; W. L. Stone et al., 2003; Toth, Dawson, Munson, Estes, & Abbott, 2003). Of particular importance, gains in verbal IQ have been observed in children with Autism beyond the preschool years (Lord, DiLavore, Shulman, Risi, & Pickles, 2003; Nordin & Gillberg, 1998; W. L. Stone et al., 2003).

EPIDEMIOLOGY

Autism was once believed to be a rare disorder, occurring at a rate of 4 to 5 in 10,000. In recent years, however, reported cases of Autism have increased significantly, leading to both public and scientific debate as to whether these estimates reflect a true increase in the number of children with this disorder, or increased awareness and detection along with a broadening definition of Autism.

Prevalence

The prevalence of Autism spectrum disorders has increased significantly in the past few decades. A large epidemiological study conducted by the Centers for Disease Control (CDC) found a prevalence rate of 34 per 10,000 among 3- to 10-year-old children in metropolitan Atlanta (Yeargin-Allsopp et al., 2003). One of the strengths of this study was sample size: 987 confirmed cases, compared to many previous studies with a median sample size of 50 (Fombonne, 2003). However, this rate of 34 per 10,000 is likely to be an underestimate. Higher-functioning individuals may have been missed, and younger children may not have been identified. Fombonne suggests that the rate reported for 5- to 8-year-olds in the CDC study—of 41 to 45 in 10,000—may be more accurate and is similar to other

surveys that report a prevalence rate of 60 per 10,000 (Baird et al., 2000; Bertrand et al., 2001; Chakrabarti & Fombonne, 2001; Fombonne, 2003). There has been public debate about a possible epidemic of Autism as rates are 3 to 4 times higher than in the 1970s. However, this apparent rise in rates may be, in part, the result of a broadening definition of Autism, particularly at the less severe end of the spectrum; methodological differences in surveys of prevalence, particularly in methods for case finding (e.g., relying on single versus multiple sources for case identification); and an increasing use of the diagnosis of Autism so that families can take advantage of federally mandated early intervention programs (Fombonne, 2003).

Gender

Autism affects males at rates 3 to 4 times higher than females (Fombonne, 1999; Volkmar et al., 1993; Yeargin-Allsopp et al., 2003). However, when females are affected, they more often fall in the severe mental retardation range (IQ < 35) and exhibit more severe symptomatology than males with the disorder (Volkmar et al., 1993). Further, the recurrence risk rate for siblings of females with Autism is twice that of siblings of males with Autism (Jorde et al., 1990).

Socioeconomic Status and Culture

Autism affects individuals at all socioeconomic levels (Fombonne, 1999, 2003; Steffenburg & Gillberg, 1986; Wing & Gould, 1979) and in all parts of the world, including Canada (Bryson, Clark, & Smith, 1988), England (Chakrabarti & Fombonne, 2001; Wing & Gould, 1979), France (Cialdella & Mamelle, 1989; Fombonne, Bolton, Prior, Jordan, & Rutter, 1997), Sweden (Steffenburg & Gillberg, 1986), Norway (Sponheim & Skjeldal, 1998), Iceland (Magnusson & Saemundsen, 2001), Japan (Honda, Shimizu, Misumi, Nimi, & Ohashi, 1996; Sugiyama & Abe, 1989), Hong Kong (Chung, Luk, & Lee, 1990), Russia (Lebedinskaya & Nikolskaya, 1993), and Croatia (Bujas-Petkovic, 1993).

SYMPTOM PRESENTATION

Symptoms of Autism include impairments in the broad domains of social interaction, play, language and communication, and a restrictive range of interests and activities.

Specific symptoms in each of these broader domains are described next.

Impairments in Social Interaction

Although symptom presentation varies widely across individuals and across the life span, impairments in social attention are a primary early feature of the disorder. It has been hypothesized that a lack of normal attention to social stimuli, such as faces, voices, and emotional expressions, deprives the child with Autism of social information input during the 1st years of life, disrupting normal brain and behavioral development as well as subsequent social development (Mundy & Neal, 2001). Such impairments in social attention, particularly joint attention skills, are believed to also impede the development of language (Bono, Daley, & Sigman, 2003; Carpenter, Nagell, & Tomasello, 1998; G. Dawson, Toth, et al., 2004; Mundy, Sigman, & Kasari, 1990; Rogers & Hepburn, 2003; Sigman & Ruskin, 1999; Tomasello & Farrar, 1986).

One theory that has been proposed to explain the social attention impairments in Autism is that these impairments are the result of an underlying impairment in social motivation, or a failure to find social stimuli inherently rewarding (G. Dawson, Toth, et al., 2004; G. Dawson, Webb, et al., 2002; Mundy & Neal, 2001). According to this view, the preferential attention to social stimuli (faces, emotional expressions, voices) that is typically present very early in life is most often accompanied by affective sharing between infant and caregiver. This mutual exchange of positive affect during episodes involving eye contact is inherently rewarding to the typically developing toddler and serves to motivate the child to notice and attend to social and affective cues. It is hypothesized that the child with Autism fails to find eye-to-eye gaze inherently rewarding and is therefore less motivated and less likely to attend to social stimuli, make meaning out of others' emotional expressions, and participate in early social exchanges. As a result, the child with Autism has fewer opportunities to engage in acts that allow for the acquisition and development of social communication and language skills.

Social Orienting Impairments

Perhaps the first social attention impairment in Autism is a lack of normal "social orienting," namely, the tendency to spontaneously orient to naturally occurring social stimuli in one's environment (G. Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998). In typical development, infants de-

vote particular attention to social stimuli, including faces, voices, and other aspects of human beings (Rochat & Striano, 1999). Indeed, by 6 months of age, typically developing infants will actively orient (i.e., turn head and/or eyes) to novel stimuli, particularly social stimuli (e.g., being called by name; Trevarthen, 1979). Children with Autism, however, exhibit early impairments in social orienting. Home videotape studies of infants later diagnosed with Autism (Osterling & Dawson, 1994; Osterling et al., 2002; Werner et al., 2000) revealed social attention impairments, including a failure to look at others and orient to their name in 12-month-olds, and a failure to orient to name in 8- to 10-month-old infants. In two experimental studies of preschool children with Autism and mental age-matched children with developmental delay, children with Autism more frequently failed to orient to both social and nonsocial stimuli, but the impairment was more severe for social stimuli (G. Dawson, Meltzoff, & Osterling, 1995; G. Dawson, Toth, et al., 2004).

Joint Attention

Joint attention behaviors include sharing attention to an object or event (e.g., through the use of alternating eye gaze), following the attention of another (e.g., following a gaze or point), and directing attention (e.g., showing and pointing to objects/events). Some infants display some aspects of joint attention (e.g., matching direction of mother's gaze to a visible target) as early as 6 months of age (Morales, Mundy, & Rojas, 1998), and most infants display all of these skills by 12 months of age (Carpenter et al., 1998; Leekam & Moore, 2001). Research has established joint attention ability as a core social-communication impairment in children with Autism, present by 1 year of age and incorporated into the diagnostic criteria for the disorder (Mundy et al., 1986; *DSM-IV*, American Psychiatric Association, 1994). Impairments in joint attention skills have been found to distinguish preschool-age children with Autism from those with typical and delayed development (Bacon, Fein, Morris, Waterhouse, & Allen, 1998; Charman et al., 1998; G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; G. Dawson, Munson, et al., 2002; Mundy et al., 1986). Additionally, impairments in protodeclarative joint attention behaviors (e.g., pointing to show, sharing) seem to be more severe than impairments in protoimperative joint attention behaviors (e.g., pointing to make a request) in children with Autism (Mundy et al., 1986, 1990; Sigman, Mundy, Sherman, & Ungerer, 1986). Joint attention ability is predictive of both concurrent language ability and future gains in expressive language skills for children with Autism (Mundy et al., 1990; Mundy, Sigman, Ungerer, & Sherman,

1987; Sigman & Ruskin, 1999; Toth et al., 2003). Taken together, these findings suggest that joint attention ability is a pivotal skill in Autism as it appears to lay a foundation for the development of more complex abilities, such as pretend play, language, and theory of mind (Charman, 1997, 2003; Mundy & Crowson, 1997; Sigman, 1997).

Face Recognition

At birth, typically developing infants display a visual preference for the sounds, movements, and features of the human face (Goren, Sarty, & Wu, 1975; Maurer & Salapatek, 1976; Morton & Johnson, 1991). Very early in life, infants are not only able to recognize their mother's face (Bushnell, Sai, & Mullin, 1989), but they can also discriminate some facial expressions (Nelson, 1993). Children with Autism, however, do not show this same preference for and fascination with faces. Osterling and Dawson (1994) found in a study of home videotapes that a failure to look at others' faces best discriminated 12-month-olds with Autism from 12-month-old typically developing infants.

Face matching and face recognition impairments have been found across a number of studies in both children and adults with Autism (Boucher & Lewis, 1992; Boucher, Lewis, & Collis, 1998; Ciolotti, Robinson, Blair, & Frith, 1999; Hauck, Fein, Maltby, Waterhouse, & Feinstein, 1998; Jambaque, Mottron, Ponsot, & Chiron, 1998; Klin et al., 1999; Ozonoff, Pennington, & Rogers, 1990; Tantam, Monaghan, Nicholson, & Stirling, 1989; Teunisse & DeGelder, 1994). Using electrophysiological measures, G. Dawson and colleagues (G. Dawson, Carver, et al., 2002; McPartland, Dawson, Carver, & Panagiotides, 2001a, 2001b) showed that 3- to 4-year-old children with Autism failed to show a differential brain electrical response to mother's versus stranger's face, as did children with delayed and typical development. Interestingly, however, the children with Autism did show greater event-related potential (ERP) responses to the familiar versus unfamiliar object, similar to the pattern of responses shown by chronological age-matched typical children. This finding suggests that, in children with Autism, the recognition memory impairment is specific to faces and that this impairment is present by at least 3 years of age.

Other studies have shown that individuals with Autism process faces differently from controls (Celani, Battacchi, & Arcidiacono, 1999; Davies, Bishop, Manstead, & Tantam, 1994). For example, whereas typically developing individuals tend to focus on the eyes when processing faces, individuals with Autism often focus on the mouth (Klin, Jones, Schultz, Volkmar, & Cohen, 2002; Klin et al., 1999; Langdell, 1978). Additionally, individuals with Autism do

not show the typical difficulty in processing inverted as opposed to upright faces (Hobson, Ouston, & Lee, 1988; Langdell, 1978; McPartland et al., 2001a, 2001b). In a recent ERP study, high-functioning adolescents and adults with Autism were shown to exhibit longer latencies of the N170 (face-specific) ERP component as compared to IQ-matched adolescents and adults. In addition to overall slower processing of face stimuli, the individuals with Autism showed similar ERP patterns in response to upright versus inverted faces and did not show the right-lateralized ERP that is found in typical individuals (McPartland et al., 2001a, 2001b).

Functional magnetic resonance imaging (fMRI) techniques have also been used to study face processing in Autism. Schultz et al. (2000) found that when individuals with Autism were shown pictures of faces, they showed less activation in the fusiform gyrus, a specialized region of the brain devoted to face processing, than in the inferior temporal gyri, a region of the brain that is typically used to process objects. Future research is needed to explore the connection between abnormalities in face processing and other social attention impairments in Autism.

Emotion Recognition and Expression

In typical development, infants are able to recognize and express emotions at a very young age. At 6 months of age, infants respond differentially to happy versus sad expressions (Cohn, Campbell, Matias, & Hopkins, 1990; Termine & Izard, 1988). At 12 months, infants are able to modulate their own behavior in response to the emotions expressed by their mother, approaching an object when mother displays a joyful expression but not when she displays a fearful expression (Klinnert, Campos, Sorce, Emde, & Svejda, 1983). By the end of the 2nd year of life, children are beginning to talk about emotions and can label simple emotions, such as happy, mad, and sad (Bretherton & Beeghly, 1982; Smiley & Huttenlocher, 1989). Children with Autism, however, generally do not exhibit this typical pattern of emotional development. A number of studies have shown that children with Autism are impaired on tasks requiring recognition and matching of emotional faces and responding to the emotional displays of others (Bormann-Kischkel, Vilsmeier, & Baude, 1995; Celani et al., 1999; G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; G. Dawson, Toth, et al., 2004; Hobson, Ouston, & Lee, 1989; Loveland et al., 1997; Sigman, Kasari, Kwon, & Yirmiya, 1992; Sigman, Ungerer, Mundy, & Sherman, 1987). Baron-Cohen, Spitz, and Cross (1993) reported that children with Autism are able to recognize simple emotions, such as happy and sad, which are typically caused by situations, but show

greater difficulty than controls in recognizing surprise, which is typically caused by beliefs. Others, however, have shown that emotion recognition impairments may not be specific to Autism, but related rather to verbal memory and performance IQ (Buitelaar, van der Wees, Swaab-Barnveld, & van der Gaag, 1999). In a study of children and adolescents ages 8 to 18, no differences were found between children with Autism and age- and verbal IQ-matched ADHD controls on emotion matching and emotion recognition tasks (Buitelaar et al., 1999).

In one of the earliest studies of emotional expression in Autism, children with Autism were found to exhibit significantly more negative emotions as well as incongruous blends of emotion as compared to typical controls (Yirmiya, Kasari, Sigman, & Mundy, 1989). Further, children with Autism failed to show positive affect even in situations where positive affect is typically displayed, such as in joint attention interactions (Kasari, Sigman, Mundy, & Yirmiya, 1990). Dawson, Hill, Spencer, Galpert, and Watson (1990) examined mother-child interactions and found that children with Autism smiled as frequently as receptive language age-matched typically developing children, but were less likely to combine smiles with eye contact or to smile reciprocally. These authors proposed that children with Autism may have a specific impairment in their ability to engage in affective sharing experiences. When talking about emotion, children with Autism required more time and more prompts, and their responses were more scripted, as compared to age-matched typically developing controls (Capps, Yirmiya, & Sigman, 1992). Finally, although individuals with Autism are able to spontaneously display facial expressions, Loveland et al. (1994) reported that they showed a particular difficulty producing affective expressions upon request without a model.

Many studies that have assessed emotion perception in children with Autism have required language, making results difficult to interpret. G. Dawson and colleagues (G. Dawson, Webb, Carver, Panagiotides, & McPartland, 2004) used ERPs to determine whether 3- to 4-year-old children with Autism Spectrum Disorder exhibited differential brain responses to a fear versus a neutral facial expression, present in typical development by 7 months of age. It was found that children with ASD did not show the typical difference in amplitude of an early ERP component to the fear versus neutral face, indicating early differences in neural processing of emotion in Autism.

Imitation

Meltzoff and Moore (1977) demonstrated that newborns are able to imitate facial expressions, which suggests that

this is an innate ability. Children with Autism, however, show impairments in both immediate and deferred motor imitation (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; Sigman & Ungerer, 1984; W. L. Stone et al., 1997). Of particular importance, imitation skills in children with Autism have been shown to predict later social and language learning (Charman et al., 2000, 2003; W. L. Stone et al., 1997; W. L. Stone & Yoder, 2001). In one study, body imitation was found to predict expressive language ability, whereas object imitation predicted play skills (W. L. Stone et al., 1997). Additionally, it has been theorized that a failure to engage in social imitative play may interfere with the development of joint attention, social reciprocity, and later theory of mind abilities (G. Dawson, 1991; Meltzoff & Gopnick, 1993; Rogers & Pennington, 1991).

Theory of Mind

The ability to infer mental states, including intentions, memories, and beliefs, and to then use this information to understand and predict the behavior of others is “one of the quintessential abilities that makes us human” (Baron-Cohen, 2000, p. 3; see also Whiten, 1993). This ability is referred to as “theory of mind” and typically develops between 3 and 5 years of age (Flavell, 1999; Wellman, 1993; Wellman, Cross, & Watson, 2001). Children with Autism, however, show impairments on standard theory of mind tasks, such as false-belief tasks that require the child to infer what another person will think or do (Baron-Cohen, 2000; Baron-Cohen, Leslie, & Frith, 1985; Peterson, 2002). In one study, children were required to attribute beliefs to a puppet that differed from their own (Baron-Cohen et al., 1985). Only 20% of the children with Autism were able to do so, compared to 86% of children with Down syndrome and typical development. Interestingly, preschool-age children with Autism have been shown to outperform typically developing preschoolers on a particular form of theory of mind task, the false-drawing task (Peterson, 2002). In this task, children with Autism were asked to draw a red apple with a green pen. When they were finished, a green apple was placed next to the red apple and the children were then told that another child would be coming in the room and asked which apple was drawn. The children with Autism were then asked the false-belief test question, “What will he say?” One possible explanation for this superior understanding of false belief in a drawing context is that children with Autism may be able to gain early insight into mental states in relation to familiar and nonverbal activities such as drawing, even when fully developed theory of mind is absent (Peterson, 2002). Some have argued that theory of mind development in

Autism is not only delayed but is qualitatively different from the typical pattern of development. For instance, in a study of children with PDD-NOS who were given a story-book theory of mind task, the children with PDD-NOS showed specific difficulties in understanding and predicting others' emotions but were able to predict actions from beliefs and desires (Serra, Loth, van Geert, Hurkens, & Minderaa, 2002). Zelazo, Jacques, Burack, and Frye (2002) examined rule-based reasoning in conjunction with theory of mind tasks in older children and adolescents with Autism and found that, for severely impaired individuals, theory of mind performance was unrelated to rule use. However, in less severely impaired individuals, the correlation between theory of mind and rule use was high. These findings suggest that poor performance on theory of mind tasks may be related to a general difficulty in using rules to integrate two incompatible perspectives. Some researchers have proposed that theory of mind deficits are primary in Autism and at the root of the difficulties observed in social interaction and communication (Baron-Cohen et al., 1985); others argue that theory of mind abilities hinge on earlier developing social communication skills, such as joint attention (Mundy & Sigman, 1989).

Play and Language

Impairments in symbolic play, language, and communication skills are present at an early age in individuals with Autism.

Symbolic Play

Representational, or symbolic, play typically emerges between 14 and 22 months of age and includes using an object to represent another object (e.g., a block to represent a car), using absent objects as if they were present (e.g., food that does not exist), or animating objects (e.g., pretending that stuffed animals can talk; Leslie, 1987). In children with Autism, symbolic play is often absent at 18 months of age (Baron-Cohen et al., 1996) or is delayed relative to mental age-matched developmentally delayed and typical children (Charman et al., 1998; G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; Mundy et al., 1987; Wing & Gould, 1979). For those children with Autism who do acquire symbolic play skills, their level of symbolic play often remains below that of their language abilities (Amato, Barrow, & Domingo, 1999; Ungerer, 1989; Wing, 1978) and is often less diverse and elaborate compared to that of developmentally delayed and typical children (Ungerer & Sigman, 1981). Further, symbolic play has been associated with both concurrent language and later social ability in young

children with Autism (Sigman & Ruskin, 1999). There exists some controversy as to the cause of this impairment; some believe that it results from impairments in joint attention and understanding others, whereas others believe it hinges on deficits in symbolic thinking and executive functioning (Charman, 1997).

Language Ability

The acquisition and development of language in Autism is often delayed and/or deviant, with approximately 30% of individuals never acquiring spoken language (Bryson, 1996; Lord & Paul, 1997). This is hardly surprising given that individuals with Autism often show early impairments in symbolic play, imitation, and joint attention, which have been shown to predict language ability. In addition to delays in language acquisition, persons with Autism often exhibit atypical speech patterns, including immediate or delayed echolalia (i.e., verbatim repetition of words or phrases), unusual prosody (e.g., atypical intonation, rhythm, stress, and volume), and pronoun reversal (e.g., “you want a drink” instead of “I want a drink”), which can persist into adulthood (Cantwell, Baker, Rutter, & Mawhood, 1989; Kanner, 1943; Lee, Hobson, & Chiat, 1994).

Moreover, individuals with Autism exhibit impairments in both the pragmatic and the semantic aspects of language (Kjelgaard & Tager-Flusberg, 2001; Lord & Paul, 1997; Tager-Flusberg, 1993, 1999, 2001). Pragmatic impairments include difficulty maintaining an appropriate level of detail (e.g., often providing excessive or irrelevant details), speaking in a pedantic manner, and difficulties in reciprocity, characterized by a failure to respond to questions and comments initiated by the other person, a tendency to monopolize the conversation (generally associated with perseveration on favorite topics), and difficulties staying on topic (i.e., often inserting random and tangential comments; Capps, Kehres, & Sigman, 1998; Eales, 1993; Tager-Flusberg, 1999, 2001). Some (Eales, 1993; Tager-Flusberg, 1993, 1996) have argued that these pragmatic impairments, as well as abnormal pronoun use, are related to deficits in perspective taking (i.e., understanding another person's intentions).

Children with Autism also show impairments in how effectively they use language. In studies comparing children with Autism to children with Down syndrome matched on age and expressive language ability, children with Autism showed less variety in their use of nouns, verbs, and adjectives and used language less often to provide or elicit information (Howlin, 1984; Tager-Flusberg, 1993, 1999). Further, Kjelgaard and Tager-Flusberg (2001) found that

children with Autism who had impaired language demonstrated better vocabulary relative to higher-order language abilities, with poor performance on phonological processing and difficulties in marking tense, similar to children with specific language impairment. Finally, in their comprehension of language, children with Autism often rely on syntax as opposed to semantic content when deciphering the meaning of a sentence (Paul, Fischer, & Cohen, 1988) and often interpret what is said to them in a concrete and literal manner (e.g., “It’s raining cats and dogs”).

For a discussion of overlap between language impairment in Autism and specific language impairment, see the earlier section on Diagnosis.

Restricted, Repetitive Interests and Behaviors

The third symptom domain in Autism is a restricted range of behaviors, activities, and interests. Such behaviors include repetitive, stereotypic motor movements, including hand flapping, finger flicking, and complex whole-body movements, such as toe-walking and spinning, as well as persistent preoccupation with parts of objects or repetitive and nonfunctional use of objects (e.g., spinning wheels, lining things up; Campbell et al., 1990; Turner, 1999; Wing, 1988; Wing & Gould, 1979). More elaborate and complex ritualistic interests and behaviors can include precise arrangement of objects; insistence on a particular sequence of actions (i.e., compulsions); adherence to sameness in terms of routine, structure, and ordering of physical space; and intense and focused preoccupations relating to particular topics and typically involving memorization of facts (e.g., movies, camera models). Preoccupations with specific topics are often seen in high-functioning individuals (Campbell et al., 1990; Turner, 1999; Wing, 1988; Wing & Gould, 1979).

Studies that have attempted to identify the earliest emerging impairments in Autism (i.e., within the first 12 months of life) have not shown stereotypic motor movements or intense interests to be commonly present at that early age (Baron-Cohen et al., 1996; Osterling & Dawson, 1994; Robins et al., 2001). Further, young, typically developing children and children with other developmental disabilities, including mental retardation and Obsessive-Compulsive Disorder, often exhibit distress due to changes in routine and a preference for sameness (Evans et al., 1997). However, what may be specific to Autism is the number and severity of these symptoms (Charman & Swettenham, 2001).

Other Related Behaviors

The following behaviors are also common in Autism, although the number and severity of these symptoms varies across individuals.

Sensory Issues

Persons with Autism often seek sensory stimulation or have heightened negative responses to sensory stimuli. For instance, children with Autism may exhibit strong negative reactions to sounds that would not affect most individuals, such as the vacuum cleaner or noises at a distance. They may also exhibit a hypersensitivity to touch, including the feel of tags in clothing or a light embrace, while at the same time appearing insensitive to pain or showing a preference for deep pressure (e.g., tight hugs). Other children may repetitively seek out certain textures (e.g., hair, metal), touch objects to their tongue, or peer at objects out of the corner of their eyes. These sensory issues can be mild or can take up a large amount of time, interfering with family activities and/or the child’s social functioning. Ornitz (1989) has argued that an impairment in the ability to modulate sensory information can lead to both under- and over-reactivity to sensory stimuli.

Attention Impairments and Hyperactivity

Estimates of overactivity and/or attentional problems in Autism range from 21% to 72% (Lainhart, 1999). Children with Autism often lack attention to people and to activities that others want them to focus on, but then show overly focused attention on objects or other nonsocial stimuli. Hyperactivity in Autism appears to decrease with age but can persist into adulthood in some individuals (Kobayashi & Murata, 1998). Certain medications may improve attention and decrease hyperactivity in some children, but more controlled studies are needed (McDougle, 1998).

Self-Injurious Behaviors

Self-injurious behaviors include biting, scratching, head banging, and hair pulling and are often an expression of frustration (Donnellan, Mirenda, Mesaros, & Fassbender, 1984; Lainhart, 1999). In a recent study of 222 children with Autism under age 7, 50% demonstrated self-injurious behaviors, with as many as 15% showing severe behaviors (Baghdadli, Pascal, Grisi, & Aussilloux, 2003). Risk factors for self-injurious behaviors include lower chronological age, more severe symptoms of Autism, and more severe delays in daily living skills (Baghdadli et al., 2003). Others

have argued that these behaviors are related to level of cognitive functioning (J. Dawson, Matson, & Cherry, 1998).

Sleep and Eating Problems

Rates of sleep disturbances in Autism have been estimated to range from 11% to 65% (Chung et al., 1990; Rutter & Lockyer, 1967; Taira, Takase, & Sasaki, 1998), with average age of onset being 2 years, 3 months (Taira et al., 1998). The most common problems are difficulty falling asleep, frequent awakening, and waking early in the morning (Taira et al., 1998). Approximately 20% of adults with Autism also exhibit sleep problems (Kobayashi & Murata, 1998). However, sleep difficulties in children with Autism appear to occur at rates similar to those found in children with other psychiatric disorders (Rutter & Lockyer, 1967) and are thus not unique to Autism.

There are frequent clinical reports of restricted eating and unusual food preferences in Autism. For instance, some individuals with Autism will eat only a few foods or will eat only foods of a certain texture, color, or taste. Others exhibit rigidity at meal times, such as insisting on eating only certain brands of foods or using only certain utensils. Although eating problems can persist into adulthood, they do tend to improve as children grow older (Rutter, 1970).

ETIOLOGY

Over the past 25 years, considerable evidence has accumulated implicating genetic factors in Autism. Environmental factors and gene-environment interactions likely also contribute to the development of this disorder.

Environmental Risk Factors

Understanding environmental influences in Autism is important for several reasons. First, a better understanding of environmental factors that contribute to the disorder could help to confirm or refute reports of geographic clusters of Autism and an overall increase in rates of Autism. Second, environmental influences may help to shed light on the neurobiology of Autism. Finally, environmental factors would help to account for the high degree of heterogeneity observed in the disorder (Rodier & Hyman, 1998).

An increased rate of Autism has been reported in children who were exposed to rubella infection in the first trimester (Chess, 1977). It is likely that exposure to infectious diseases such as rubella during prenatal development may increase the risk of Autism by adding to other etiolog-

ical factors, such as genetic predisposition (Rodier & Hyman, 1998). Many studies have investigated whether general suboptimal conditions (complications) during pregnancy, delivery, or infancy may contribute to Autism. No single factor has emerged consistently, and individual adverse events appear to have minimal impact (Bolton et al., 1994, 1997; Bryson et al., 1988; Gillberg & Gillberg, 1983; Levy, Zoltak, & Saelens, 1988; Lord, Mulloy, Wendelboe, & Schopler, 1991). In studies of individuals with high-functioning Autism, only one factor, a gestation period of more than 42 weeks, was found to be associated with the disorder (Lord et al., 1991). Piven et al. (1993) found that first- or fourth-born children had Autism more often than their siblings. Others have found no differences on pre- and perinatal optimality measures when comparing the births of children with Autism to those of typically developing children (Cryan, Byrne, O'Donovan, & O'Callaghan, 1996). Bolton and colleagues (1997) have concluded that optimality factors are not likely to play a direct role in Autism. Such factors are more likely related to extant fetal abnormalities, genetic factors (Bolton et al., 1994, 1997), or possibly to teratologic factors (Rodier & Hyman, 1998). Teratogenic exposure to thalidomide has been associated with Autism (Miller & Strömmland, 1993). These researchers found that 5 of 15 thalidomide cases that had exposure between the 20th and 24th days of gestation had Autism, a rate of 33% during this critical period in prenatal development. Prenatal exposure to valproic acid (Moore et al., 2000; J. Williams, Whiten, Suddendorf, & Perrett, 2001) and cocaine (Davis et al., 1992) may also increase the risk of Autism.

In the late 1990s, it was proposed that a new variant of Autism caused by immunization with the combined measles, mumps, and rubella vaccine was responsible for the increase in rates of the disorder (Wakefield, 1999; Wakefield et al., 1998). These claims were made based on a sample size of 12 children with Pervasive Developmental Disorder who were referred for the evaluation of gastrointestinal diseases associated with developmental regression. A number of epidemiological studies since then have failed to confirm an association between the MMR vaccine and Autism (for reviews, see Dales, Hammer, & Smith, 2001; Farrington, Miller, & Taylor, 2001; Fombonne & Chakrabarti, 2001; Kaye, del Mar Melero-Montes, & Jick, 2001; E. N. Taylor et al., 1999; Wilson, Mills, Ross, McGowan, & Jadad, 2003). In addition, Andrews et al. (2002) have found that parents of children with Autism with regression, who were diagnosed after the publicity alleging the link between the MMR vaccine and Autism, tended to

recall onset shortly after the vaccine more often than parents of similar children who were diagnosed prior to the publicity. Thimerosal, a preservative containing ethyl mercury that is added to many vaccines, has also come under scrutiny. In 1999, the FDA determined that infants receiving multiple vaccines might be exposed to greater levels of mercury than is recommended. Although a recent review found no evidence of harm from thimerosal in vaccines (Ball, Ball, & Pratt, 2001), thimerosal-free vaccines are now available for all routine childhood immunizations (Kimmel, 2002). Several studies are currently under way examining the effects of thimerosal on childhood disorders.

Genetic Risk Factors

Next, we review what is known about genetic factors in Autism.

Single Gene Disorders

Five to 10% of Autism cases are due to an identifiable medical disorder with a known inheritance pattern, including Fragile X syndrome, untreated phenylketonuria (PKU), tuberous sclerosis, and neurofibromatosis (Szatmari, Jones, Zwaigenbaum, & MacLean, 1998). Fragile X syndrome in particular accounts for about 8% of cases of Autism (Smalley, Asarnow, & Spence, 1988).

Twin and Family Studies

A number of twin studies have provided evidence of a strong genetic component to Autism (Bailey, Le Couteur, Gottesman, & Bolton, 1995; Folstein & Rutter, 1977; Le Couteur, Bailey, & Rutter, 1989; Ritvo, Freeman, Mason-Brothers, Mo, & Ritvo, 1985; Steffenburg et al., 1989). These studies have shown a higher concordance rate for Autism in monozygotic (MZ), or identical, twin pairs than in dizygotic (DZ), or fraternal, twins. In their seminal study, Folstein and Rutter reported that 36% of MZ twins were concordant for Autism, as compared to 0% of DZ twins. When they included related social or cognitive impairments, such as reading disability, language delay, articulation disorder, and mental handicap, 82% of the MZ twins and 10% of the DZ twins were concordant for Autism. A more recent study found that 60% of MZ twins were concordant for the full syndrome of Autism, and more than 90% were concordant when related social and cognitive impairments were included (Bailey et al., 1995). Heritability estimates are quite high, ranging from 91% to 93% (Bailey et al., 1995).

Family studies have provided further evidence of the heritability of Autism. The likelihood of having a second

child with Autism has been estimated at 4.5% (Jorde et al., 1990, 1991), which is 45 to 90 times greater than the population risk (Cook, 1998). Further, the recurrence risk rate for siblings of females with Autism is twice that of siblings of males with Autism (Jorde et al., 1990). Recurrence risk rates following the birth of a second child with Autism range from 16% to 35% (Szatmari et al., 1998). Autism rates in second- (0.18%) and third- (0.12%) degree relatives are much lower (Szatmari et al., 1998). This sharp decrease in risk rates from first- to second- and third-degree relatives indicates that Autism is most likely the result of multiple gene (5 to 10 or more) interactions (Jorde et al., 1990; Pickles et al., 1995; Risch et al., 1999).

Broader Autism Phenotype

A broader Autism phenotype, or “lesser variant” of Autism, is defined as having one or more difficulties in social functioning, communication, cognition, and interests/behaviors (Baron-Cohen & Hammer, 1997). Broader phenotype studies have been on the rise in recent years and have examined characteristics of first-, second-, and third-degree relatives of individuals with Autism. As many as 10% to 25% of siblings who do not meet criteria for Autism demonstrate broader phenotype impairments, including learning difficulties, language and communication deficits, and social impairments (Bolton et al., 1994; Bolton & Rutter, 1990). A more recent study reported that 12% of siblings and 10% of parents exhibited broader phenotype characteristics (Starr et al., 2001).

Parents of children with Autism were 3 times as likely as parents of children with Down syndrome to have had definite or probable language problems in childhood, including articulation deficits, trouble learning to read, or trouble with spelling, and showed a significant split between verbal and performance IQ scores relative to controls (Folstein et al., 1999). A study of personality traits in first-degree relatives found that relatives of individuals with Autism were more anxious, impulsive, aloof, shy, sensitive, irritable, and eccentric than relatives of individuals with Down syndrome (Murphy et al., 2000). In this same study, three factors were derived for the Autism group: withdrawn, difficult, and tense. The authors concluded that the withdrawn and difficult factors appeared to reflect social functioning impairments, whereas the tense factor appeared to be related to the burden of raising a child with Autism. In multiplex families (i.e., those with two or more children with Autism), parents of children with high rates of repetitive behaviors showed significantly more obsessive-compulsive traits and were more likely to have Obsessive-Compulsive

Disorder than parents of children with low repetitive behavior scores (Hollander, King, Delaney, Smith, & Silverman, 2003). Still other studies have reported increased rates of pragmatic language impairments (Landa et al., 1992) and executive function deficits (e.g., set shifting and planning; Hughes, Plumet, & Leboyer, 1999) and difficulties in reading comprehension and rapid automatized naming (Piven & Palmer, 1997) in family members.

In second- and third-degree relatives, Szatmari et al. (2000) found that 10% demonstrated communication impairments, 7% exhibited repetitive activities, 14% showed social impairments, 23% met criteria for the "broad" definition of the lesser variant, and 7% met criteria for the "narrow" definition of the lesser variant, as defined by Bolton et al. (1994).

Like Autism, broader phenotype characteristics are much more common in males than females, although this is less true of the mildest cases, and are usually evident in early childhood (Bailey, Phillips, & Rutter, 1996). However, unlike Autism, individuals with broader phenotype characteristics are generally of normal intelligence, and no association with epilepsy has been found (Bailey et al., 1996). Some researchers have proposed that the broader phenotype is simply a lower dose of the genetic predisposition to Autism, whereas others argue a "two-hit" mechanism. In this view, one set of factors predisposes the individual to the broader phenotype, and a separate set of factors is involved in the development of Autism (Bailey et al., 1996). In any case, these findings in the broader phenotype literature suggest that incorporating quantitative measures of autistic traits that may be expressed to a lesser degree in relatives may be useful in studies of the genetic basis of Autism.

Sibling Linkage and Quantitative Trait Locus Analyses

Sibling linkage studies use highly variable polymorphisms spaced evenly throughout the genome to identify chromosome regions that are shared among siblings with Autism. Thus far, findings from Autism linkage studies have been inconsistent. Possible susceptibility regions include chromosomes 1p, 2q, 7q, 13q, 16p, and 19q (Alarcon, Cantor, Liu, & Gilliam, 2002; Ashley-Koch et al., 1999; Bailey et al., 1998; Barrett et al., 1999; Bradford et al., 2001; Buxbaum et al., 2001; International Molecular Genetic Study of Autism Consortium, 1998, 2001; Liu, 2001; Philippe et al., 1999; Risch et al., 1999). Only regions 2q and 7q have been implicated in more than one study, with chromosome 7 appearing the most promising (Ashley-Koch et al., 1999; Barrett et al., 1999; Collaborative Linkage Study of Autism, 2001). Chromosome 7 has been linked

both to Autism and to language disorders, such as specific language impairment (Folstein & Mankoski, 2000; Warburton et al., 2000). In addition, the 7q31 region contains other genes of interest, including the serotonin receptor gene and the reelin gene (see section on Candidate Gene Studies).

Quantitative trait loci (QTL) refer to genetic loci that modify the expression of a phenotypic trait in a continuous rather than categorical way. In a study of multiplex families that included parent and proband language phenotypes, Bradford et al. (2001) found that the highest signals, on chromosome 7q and 13q, were primarily accounted for by families in which both probands exhibited language delay. Similarly, a nonparametric multipoint linkage analysis of 152 families from the Autism Genetic Resource Exchange that included QTL from the Autism Diagnostic Interview ("age at first word," "age at first phrase," and a composite of "repetitive and stereotyped behavior") revealed the most robust QTL results for "age at first word" on chromosome 7q (Alarcon et al., 2002).

Autism and Specific Language Impairment

Both Autism and SLI are highly heritable, complex genetic disorders (Santangelo & Folstein, 1999; Tallal & Benasich, 2002; Tomblin & Zhang, 1999) that involve several genes. In addition, family studies have distinguished a broader phenotype. In family members of persons with Autism, elevated rates of language-related impairments have been found, including language delay and language-related learning deficits (Bolton et al., 1994; Fombonne et al., 1997; Piven & Palmer, 1997). Among siblings of persons with SLI, there is an elevated risk of Autism (Tomblin, Hafeman, & O'Brien, 2003). In addition, genetic studies have reported linkage to the same region on chromosome 7 for both disorders (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998; International Molecular Genetic Study of Autism Consortium, 1998). Therefore, it is possible that families with SLI and Autism share some of the same genetic and phenotypic characteristics. Future research that targets the subgroup of children with Autism who exhibit those aspects of language impairment that are also characteristic of SLI may be useful in defining the genetic phenotype of Autism.

Candidate Gene Studies

Numerous candidate gene studies in Autism have been conducted, with little success thus far. Here, a few of such studies are reviewed.

Increased blood and urinary serotonin levels and the positive effect of selective serotonin reuptake inhibitors (SSRIs) on some symptoms of Autism (see Intervention

section later in this chapter) led to studies of genes involved in the serotonin system. Although initial studies implicated the serotonin transporter gene (Cook et al., 1997), later studies did not confirm a link (Klauck, Poustka, Benner, Lesch, & Poustka, 1997; Maestrini et al., 1999; Persico et al., 2000; Zhong et al., 1999).

Rodier, Ingram, Tisdale, Nelson, and Romano (1996) conducted an autopsy study to examine the motor nuclei in the brain stem of an individual with Autism. They found shortening of the brain stem between the trapezoid body and the inferior olive, and near-complete absence of the facial nucleus and superior olive, abnormalities similar to those reported in HoxA-1 gene knock-out mice. The HoxA and HoxD genes have also been shown to influence differentiation of the fingers and toes. One trait, the relative length of the second and fourth digits, has been found to correlate with Autism (Manning, Callow, & Bundred, 2003). These findings suggest that the Hox genes may be implicated in Autism. However, other studies have reported conflicted findings regarding an association between the HoxA-1 gene and Autism (B. Devlin et al., 2002; Gallagher, Hawi, Kearney, Fitzgerald, & Gill, 2004; Ingram et al., 2000; Li et al., 2002).

Reelin is an important secretory glycoprotein that regulates normal layering of the brain, normal cell signaling, correct axonal growth, synaptic plasticity, and programmed cell death (Adams & Cory, 1998; Fatemi, Stry, Halt, & Realmuto, 2001; Ogawa et al., 1995). Fatemi and colleagues found a decrease in the level of reelin in the autistic cerebellum, which may be responsible for some of the cognitive deficits in Autism. In another study by these same researchers (Fatemi, Stry, & Egan, 2002), a reelin 410 deficiency was observed in autistic twins and their first-degree relatives (mothers, fathers, and typically developing siblings). A genetic study of affected sib pairs did not provide support for the reelin gene as a susceptibility gene in Autism, but a family-based association study using data from the Autism Diagnostic Interview-Revised found that children with at least one large reelin gene allele (> 11 repeats) tended to have earlier onset of phrase speech (Zhang et al., 2002). Therefore, the reelin gene may play a role in the etiology of some cases of Autism. However, it should be noted that reelin has also been implicated in Schizophrenia (Fatemi, Earle, & McMenomy, 2000; Guidotti et al., 2000; Impagnatiello et al., 1998), Bipolar Disorder (Fatemi et al., 2000; Guidotti et al., 2000), Major Depression (Fatemi et al., 2000), and possibly Schizoaffective Disorder (Fatemi, Stry, & Egan, 2002). Furthermore, a more recent study found no evidence for a link between reelin and Autism (G. Devlin et al., 2004).

Future Directions

Over the past 25 years, we have achieved a deeper understanding of the genetic and environmental risk factors involved in the development of Autism. Regarding the study of genetic factors in particular, we now know that Autism cannot be attributed to a single gene, but rather, to multiple gene interactions. Each gene acts as a risk factor for an element of this complex disorder, with the greatest risk resulting from a large number of genes acting in concert. Recent research also suggests that Autism susceptibility genes may produce effects on a phenotypic continuum. Given this possibility, future research will incorporate the use of dimensional measures—behavioral and/or biological—of core Autism traits to aid in the identification of the specific genes involved in this disorder.

BRAIN FUNCTIONING AND DEVELOPMENT IN AUTISM

It is believed that the brain regions affected in Autism are disrupted early in development, very likely during the prenatal period. Brain regions hypothesized to be affected include the cerebellum, temporal lobe areas (e.g., medial temporal lobe, fusiform gyrus, superior temporal sulcus), the prefrontal cortex (both ventromedial and dorsolateral prefrontal cortex and Broca's area), and the inferior parietal cortex (Bachevalier, 1994; Baron-Cohen et al., 2000; Bauman & Kemper, 1994; Courchesne, 1989; G. Dawson, Webb, et al., 2002).

Enlarged Cerebral Volume

Increased cerebral volume is one of the earliest abnormalities in brain development apparent in children with Autism (Bailey et al., 1998; Piven, Harper, et al., 1995, 1996; Sparks et al., 2002). In a recent study by Courchesne and colleagues (Courchesne, Carper, & Akshoomoff, 2003), it was found that head circumference at birth in infants later diagnosed with Autism Spectrum Disorder was significantly smaller than that found in typically developing infants; however, between 1 to 2 months of age and 6 to 14 months of age, there was an abnormally accelerated rate of growth in head circumference in infants with ASD, more so for those with Autistic Disorder as compared to PDD-NOS. These results suggest that increased brain volume may be an early indicator of Autism, preceding the behavioral onset of the disorder (Courchesne et al., 2003). Further, Aylward, Minshew, Field, Sparks, and Singh (2002) found

that children with Autism age 12 years and younger had significantly larger brain volumes than controls; however, brain volumes for individuals with Autism over 12 years of age did not differ from controls, suggesting that there is a slight decrease in brain volume beginning in adolescence in children with Autism at the same time that typically developing children are experiencing a slight increase in volume. Although other studies have also shown brain enlargement in younger children with Autism, but not in older children or adults with Autism (Akshoomoff, Pierce, & Courchesne, 2002; Courchesne, Bartholomeusz, Karns, & Townsend, *in press*; Courchesne et al., 2001), brain enlargement has also been observed in older individuals with Autism through postmortem and imaging studies; thus, within individuals, the course of brain development may vary (Bailey et al., 1998; Bauman & Kemper, 1985; Courchesne, Muller, & Saitoh, 1999; Lainhart et al., 1997; Piven, Harper, et al., 1995; Piven et al., 1996).

Cerebellum

Neuropathological studies have found reduced numbers of Purkinje or granule cells in the cerebellum (Bailey et al., 1998; Bauman & Kemper, 1994; Raymond, Bauman, & Kemper, 1996). Courchesne (1989) has argued that loss of Purkinje cells may disrupt normal cerebellar functioning necessary for rapid shifts of attention, motor behaviors, and associative learning, and may lead to excitatory interference to brain stem and thalamic systems, which mediate attention and arousal. Early impairments in the cerebellum may also affect later development of limbic regions (Courchesne, Chisum, & Townsend, 1994).

Medial Temporal Lobe

Based on MRI of 3- to 4-year-old children with Autism Spectrum Disorder compared to those with developmental delay or typical development, Sparks et al. (2002) reported that amygdala enlargement exceeded that of overall increased cerebral volume and was related to more severe joint attention and face recognition impairments (Howard et al., 2000; Sparks et al., 2002). Right amygdala enlargement was found to predict a slower rate of growth in social and language skills between ages 3 to 4 years and 6 to 7 years for children with Autistic Disorder (Munson et al., 2004). Taken together, these findings suggest that early increased amygdala volume may be a marker of severity of Autism impairment.

Autopsy studies have revealed abnormalities of the medial temporal lobe (MTL), including the amygdala, hippocampus, and surrounding regions (Bauman & Kemper, 1994). Young children with Autism perform poorly on MTL tasks, including visual recognition memory (paired comparison, delayed nonmatched to sample) and deferred imitation tasks (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; G. Dawson, Munson, et al., 2002). It has been hypothesized that Autism might involve an impairment in other aspects of hippocampal functioning as well, such as feature binding (i.e., binding of items or events into a cohesive memory), context memory, and source memory (G. Dawson, Webb, et al., 2002). Such memory functions are important in representing social events (see H. Cohen et al., 1999; N. Cohen & Eichenbaum, 1993). An impairment in feature binding, that is, a failure to integrate information into a meaningful whole (Motttron, Belleville, & Menard, 1999; Shah & Frith, 1993), has also been demonstrated in parents of children with Autism (Happe, Briskman, & Frith, 2001) and may explain the difficulties in face processing found in Autism.

A number of studies have shown that the MTL is involved in social perception (Bachevalier, 2000; Baron-Cohen et al., 2000; G. Dawson, 1996), including recognition of faces and facial expressions (Aggleton, 1992; Jacobson, 1986; Nelson & deHaan, 1996), forming associations between stimuli and reward value (Baxter & Murray, 2000; Gaffan, 1992; Malkova, Gaffan, & Murray, 1997), recognizing the affective significance of stimuli (LeDoux, 1987), perceiving body movements, such as gaze direction (Brothers, Ring, & Kling, 1990), and certain cognitive abilities that may be important for social perception and imitation (Murray & Mishkin, 1985).

In a study by G. Dawson and colleagues (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998), MTL and prefrontal function in school-age children with Autism was assessed by using the delayed nonmatch to sample (DNMS) and delayed response tasks, respectively. They found that children with Autism were impaired on the DNMS task and the delayed response task compared to mental age-matched children with developmental delays and typical development. Severity of Autism symptoms correlated strongly with DNMS performance, but not with performance on the delayed response task. To extend this study, a more comprehensive set of neuropsychological tasks was administered to a younger and larger sample of children with Autism (G. Dawson, Munson, et al., 2002). The test battery included three tasks measuring dorsolateral prefrontal function and three tasks assessing MTL and/or MTL-

ventromedial prefrontal function. Interest in ventromedial prefrontal function was based on findings that patients with ventromedial prefrontal lesions also exhibited deficits in social cognition and theory of mind (Cicerone & Tanenbaum, 1997; Damasio, Tranel, & Damasio, 1990; V. E. Stone, Baron-Cohen, & Knight, 1998). Furthermore, fMRI studies have shown ventromedial prefrontal activation during theory of mind and social attribution tasks (Fletcher et al., 1995; Happe et al., 1996; Schultz, Romanski, & Tsatsanis, 2002).

G. Dawson, Munson, et al. (2002) examined the relationship between performance on the neuropsychological tasks and a core Autism symptom, joint attention. Results showed that the children with Autism were significantly impaired in joint attention ability compared to controls and that performance on the MTL-ventromedial prefrontal tasks was more strongly related to joint attention ability than performance on the dorsolateral prefrontal tasks. These findings suggest that core Autism symptoms, such as joint attention ability, may be related to dysfunction of the MTL-ventromedial prefrontal circuit.

A number of investigators have suggested that the severity or extent of MTL dysfunction varies across individuals with Autism and may account for the variability in functioning (Bachevalier, 1994; Barth, Fein, & Waterhouse, 1995; G. Dawson, 1996; Waterhouse, Fein, & Modahl, 1996). This idea is based on the work of Bachevalier, who found that monkeys with both hippocampal and amygdala lesions exhibited more severe memory and social impairments than monkeys with amygdala lesions alone. In individuals with Autism, memory impairments related to MTL function were found only in lower-functioning individuals (Ameli, Courchesne, Lincoln, Kaufman, & Grillon, 1988; Barth et al., 1995; Boucher, 1981; Boucher & Warrington, 1976; Rumsey & Hamburger, 1988). G. Dawson and colleagues (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998) found that children with Autism who performed fewer immediate and deferred imitative acts (hippocampal system) also required more trials to reach criterion on the DNMS, an MTL task, and exhibited more severe symptoms of Autism, such as greater joint attention impairments.

A variation on this hypothesis posits that individuals with less severe symptoms are impaired in the temporal-parietal association regions and the parietal cortex but have little or no MTL dysfunction, whereas individuals with more severe symptoms have significant MTL dysfunction that then leads to prefrontal impairments (Waterhouse et al., 1996). In this view, prefrontal impairments are the downstream consequence of faulty MTL function-

ing. In support of this hypothesis, studies with monkeys have shown that early MTL damage disrupts prefrontal cortex development (Bertolino et al., 1997; Chlan-Fourney, Webster, Felleman, & Bachevalier, 2000; Saunders, Kolachana, Bachevalier, & Weinberger, 1998). In studies of very young children with Autism (age 3 to 4), no differences in prefrontal performance were found relative to mental age-matched controls (G. Dawson, Munson, et al., 2002; Griffith, Pennington, Wehner, & Rogers, 1999). However, older elementary school-age children with Autism have demonstrated prefrontal (executive function) deficits compared to controls (G. Dawson, Meltzoff, Osterling, & Rinaldi, 1998; McEvoy, Rogers, & Pennington, 1993; Pennington & Ozonoff, 1996). These results are not surprising given that executive function ability is just emerging during the preschool period (Diamond & Goldman-Rakic, 1989). Longitudinal studies of executive function in younger, and also in more severely affected, individuals with Autism are needed to better understand the course of prefrontal dysfunction in Autism.

Abnormalities in Brain Regions Involved in Face Processing

Studies have shown that individuals with Autism are impaired in their ability to recognize and match faces (Boucher & Lewis, 1992; Boucher et al., 1998; Cipolotti et al., 1999; Hauck et al., 1998; Jambaque et al., 1998; Klin et al., 1999; Ozonoff et al., 1990; Tantam et al., 1989; Teunisse & DeGelder, 1994) and use atypical strategies for processing faces (Hobson et al., 1988; Joseph, 2001; Klin et al., 2002; Langdell, 1978). For typical individuals, the most salient parts of the face are, in order of importance, eyes, mouth, and nose (Shepherd, 1981). Individuals with Autism, however, spend more time looking at the lower half of the face rather than the eyes and are better at matching faces when matching is based on the lower half of the face as opposed to the upper face or eyes (Joseph, 2001; Langdell, 1978). Further, Klin and colleagues (2002) used eye-tracking technology to demonstrate that when viewing emotional and dramatic scenes from a movie, adults with Autism spent more time looking at mouths, bodies, and objects than eyes.

Functional MRI studies in Autism show no activation of the fusiform gyrus, a brain area specialized for face processing (Pierce, Muller, Ambrose, Allen, & Courchesne, 2001; Schultz et al., 2000), and increased activation in the frontotemporal regions, but not the amygdala, when making inferences from the eyes (Baron-Cohen, Scahill, et al.,

1999). Electrophysiological studies also have demonstrated face processing abnormalities. As mentioned in the section on Symptom Presentation, G. Dawson and colleagues (G. Dawson, Carver, et al., 2002) found that 3- to 4-year-old children with Autism failed to show differential ERPs to faces, whereas they showed normal ERPs to objects. A study of ERPs in adolescents and adults with Autism demonstrated that these individuals have slower processing of faces, fail to show a processing speed advantage for faces relative to nonface stimuli, and have atypical lateralization of ERPs to faces (McPartland et al., 2001a, 2001b).

It is possible that abnormal face processing in Autism is related to an innate abnormality in face processing regions, such as the fusiform face area and superior temporal sulcus. This would result in impairments in early stage face processing (faulty “starter set” for encoding). Alternatively, face processing impairments might be secondary to an impairment in social motivation/sensitivity to social reward. Specifically, an impairment in social motivation might result in reduced attention to faces and facial expressions. This might further lead to a failure to develop expertise in face processing (Carver & Dawson, 2002; G. Dawson, Ashman, & Carver, 2000; Dawson & Zanolli, 2003; Grelotti, Gauthier, & Schultz, 2002; Mundy & Neal, 2001). If the latter explanation is correct, then early intervention might be expected to have a significant impact on face processing development. Early intervention approaches often focus on rewarding children for looking at others and making eye contact (G. Dawson & Zanolli, 2003). Current studies are examining the impact of such early interventions on the development of face processing in children with Autism.

Brain Regions Involved in Motor Imitation

Motor imitation impairments are well documented in Autism (G. Dawson & Adams, 1984; G. Dawson & Lewy, 1989; DeMyer et al., 1972; Meltzoff & Gopnik, 1993; Rogers, 1999; Rogers & Pennington, 1991; I. M. Smith & Bryson, 1994; J. Williams et al., 2001) and may be a precursor to the development of theory of mind (Meltzoff & Gopnik, 1993). A number of brain regions are involved in imitation. For example, patients with left frontal lesions display dyspraxia (Goldenberg, 1995; Goldenberg & Haggman, 1997; Merians et al., 1997); the left hemisphere is activated during imitation of hand and facial movements (G. Dawson, Warrenburg, & Fuller, 1985), and, in animals, cells in the superior temporal sulcus code the movements of the face, limbs, and whole body (Oram & Perrett, 1994;

Perrett et al., 1984, 1985, 1989). In the prefrontal cortex in monkeys, “mirror neurons” fire when a monkey performs or views another monkey performing certain actions (Gallese, Fadiga, Fogassi, & Rizzolatti, 1996; Rizzolatti, Fadiga, Matelli, et al., 1996). Other brain areas that are important in motor imitation include the parietal and prefrontal regions (premotor cortex and Broca’s area; Grafton, Arbib, Fadiga, & Rizzolatti, 1996; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996) and the superior temporal gyrus (Decety, Chaminade, Grezes, & Meltzoff, 2002). Thus far, few, if any, functional brain imaging studies have examined patterns of brain activation during imitation in Autism; this is an area ripe for study.

Brain Regions Involved in Language

As described in the sections on Diagnosis and Etiology, some have argued that there is overlap between Autism and specific language impairment, with a subgroup of individuals with Autism showing the characteristic profile of SLI (Kjelgaard & Tager-Flusberg, 2001; Tager-Flusberg, 2003, in press; Tager-Flusberg & Joseph, 2003). MRI findings have shown that this subgroup of children with Autism has the same neurocognitive phenotype as children with SLI. Other studies of SLI have reported volumetric and asymmetry differences in the planum temporale and parietal and frontal cortex, as well as alterations in the magnocellular neurons in the lateral geniculate nucleus and medial geniculate nucleus (see Tallal & Benasich, 2002). Positron emission tomography (PET) studies of phonological processing have most consistently activated Broca’s area (Demonet et al., 1992; Paulescu, Frith, & Frackowiak, 1993; Zatorre, Evans, Meyer, & Gjedde, 1992), the secondary auditory cortex (Demonet et al., 1992; Paulescu et al., 1993; Sergeant, Zuck, Levesque, & MacDonald, 1992), and the supramarginal gyrus (Paulescu et al., 1993; Petersen, Fox, Posner, Mintun, & Raichle, 1989; Zatorre et al., 1992).

A phonological processing impairment in 3- to 4-year-old children with Autism was found in a study of speech processing using an electrophysiological mismatch negativity (MMN) paradigm (Coffey-Corina & Kuhl, 2001). In this study, the children watched a video of their choice while passively listening to two different speech sounds: One syllable, /wa/, was presented on 85% of the trials (standard), and a different syllable, /ba/, was presented on the remaining 15% of trials (deviant). Results indicated that whereas typically developing children showed a significant difference between standards and deviants, children with Autism showed no significant difference for the two

types of speech stimuli. Therefore, in some children with Autism, basic auditory-linguistic processing may be fundamentally different.

Summary

In summary, Autism involves dysfunction of multiple brain regions. Our understanding of the neural bases of Autism has increased as a result of both structural and functional brain imaging studies, many of which have only recently included younger children. Additional research, particularly longitudinal studies of brain function in individuals with Autism, is needed to better understand the complex course of brain development and function in this disorder.

NEUROCHEMICAL FINDINGS AND PHARMACOLOGICAL INTERVENTIONS

Findings from a number of studies suggest that neurochemical factors play a major role in Autism (Tsai, 1999). Studies that have examined neurotransmitters in individuals with Autism are reviewed next.

Serotonin

Serotonin is a neurotransmitter that affects a range of behaviors and processes, including sleep, appetite, learning, memory, pain and sensory perception, motor function, and early brain development and plasticity (Azmitia & Whitaker-Azmitia, 1997; Lauder, 1993; Volkmar & Anderson, 1989). Hyperserotonemia (i.e., having peripheral serotonin levels in the upper 5% of the normal distribution) has been consistently reported in about one-third of persons with Autism, with mean levels ranging from 17%–128% higher than controls (G. M. Anderson et al., 1987; G. M. Anderson, Horne, Chatterjee, & Cohen, 1990; G. M. Anderson & Hoshino, 1987; Cook et al., 1993; Herault et al., 1996; Piven et al., 1991). Using PET technology, researchers have been able to examine serotonin more directly. For instance, in a study of seven boys with Autism, a pattern of increased synthesis of serotonin in the contralateral dentate nucleus of the cerebellum and decreased synthesis of serotonin in the thalamus and frontal cortex was observed (Chugani et al., 1997). Interestingly, elevated levels of serotonin have also been observed in roughly 50% of mothers and fathers and in 87% of siblings of persons with Autism (Leboyer et al., 1999).

Dopamine

Most studies of dopamine in Autism have focused on homovanillic acid (HVA), the main metabolite of dopamine. Although results have not been consistent, some studies have found elevated HVA levels in children with Autism (Gillberg & Svennerholm, 1987). In another study, elevated HVA levels were found in more severely impaired children, especially those with more severe stereotypic and repetitive motor behaviors (Narayan, Srinath, Anderson, & Meundi, 1993). Dopamine agonists, such as stimulants, have been shown to increase stereotypies, aggression, and hyperactivity in children with Autism (Young, Kavanagh, Anderson, Shaywitz, & Cohen, 1982), which suggests that the dopamine system is involved in this disorder.

Epinephrine and Norepinephrine

Epinephrine and norepinephrine impact memory, attention, arousal, movement, anxiety, and respiratory and cardiac function (Volkmar & Anderson, 1989). Researchers have investigated the idea that increased levels of norepinephrine (a neurotransmitter and hormone) may influence symptoms of arousal and anxiety in individuals with Autism. A number of studies have found no differences between Autism subjects and controls in cerebral spinal fluid, plasma, and urinary excretion of norepinephrine's principal metabolite, 3-methoxy-4-hydroxyphenyleneglycol, or in urinary excretion rates of epinephrine, norepinephrine, and vanillylmandelic acid (Gillberg, Svennerholm, & Hamilton-Hellberg, 1983; Minderaa, Anderson, Volkmar, Akkerhuis, & Cohen, 1994; Young et al., 1982). In one study, however, both epinephrine and norepinephrine were significantly lower in the Autism group than in controls (Launay et al., 1987).

Endogenous Opioids

Endogenous opioid peptides, or endorphins, have been linked to social behaviors, emotion, motor activity, and pain perception (Panksepp & Sahley, 1987). Some researchers have suggested that elevated opioids may play a role in the self-injurious behaviors and cognitive and socioemotional deficits observed in Autism (Panksepp, 1979; Panksepp & Sahley, 1987). Thus far, however, results have been inconsistent, with some reporting increased levels of opioids (Tordjman et al., 1997) and others reporting decreased levels of endorphins in Autism (Leboyer et al., 1994; Sandman, Barron, Chicz-DeMet, & DeMet, 1990).

Pharmacological Treatments

Most of the pharmacological studies to date have been open trial (rather than controlled) studies with very small sample sizes. Nevertheless, a number of drugs have been shown to be promising in ameliorating certain symptoms of Autism. Most of these drugs target related symptoms, such as hyperactivity and self-injurious behavior, but some (e.g., SSRIs) have recently been shown to improve core social symptoms of Autism.

Serotonergic Drugs

Two groups of medications that influence the serotonin system—antidepressants and antianxiety drugs—have been studied in Autism.

SSRIs and Other Antidepressants. Medications that influence serotonin include clomipramine, fluoxetine (Prozac), fluvoxamine, and sertraline. Extant evidence suggests that these drugs may reduce hyperactivity in children with Autism (Gordon, Rapoport, Hamburger, State, & Mannheim, 1992; Gordon, State, Nelson, Hamburger, & Rapoport, 1993) and improve obsessive-compulsive symptoms, social withdrawal, reciprocal social interaction, motor stereotypies, aggression, and self-injurious behaviors (Gordon et al., 1993; Harvey & Cooray, 1995; Hellings, Kelley, Gabrielli, Kilgore, & Shah, 1996; McDougle, Price, & Goodman, 1990; Potenza & McDougle, 1997; Steingard, Zimnitzky, DeMaso, Bauman, & Bucci, 1997). However, use of these drugs can lead to serious cardiovascular side effects and lowered seizure thresholds and should therefore be prescribed with caution.

Antianxiety Drugs. In two studies of buspirone, reductions in hyperactivity were noted (McCormick, 1997; Realmuto, August, & Garfinkel, 1989). More research needs to be done on the efficacy of antianxiety drugs in treating symptoms of Autism.

Dopaminergic Drugs

Antipsychotics, including haloperidol, risperidone, and clozapine, have all been shown to produce at least moderate reductions in symptoms of hyperactivity, but effects are less clear on symptoms of impulsivity and inattention (L. T. Anderson & Campbell, 1989; L. T. Anderson et al., 1984; Campbell et al., 1978; Fisman & Steele, 1996; Horri-gan & Barnhill, 1997; Joshi, Capozzoli, & Coyle, 1988; Malek-Ahmadi & Simonds, 1998; McDougle et al., 1997; Nicolson, Awad, & Sloman, 1998; Perry, Pataki, Munoz-Silva, Armenteros, & Silva, 1997; Potenza, Holmes, Kanes,

& McDougle, 1999; Zuddas, Ledda, Fratta, Muglia, & Cianchetti, 1996). Risperidone and clozapine are both dopamine and serotonin receptor antagonists.

Epinephrine- and Norepinephrine-Related Drugs

Clonidine is an adrenergic receptor agonist that decreases norepinephrine neurotransmission (Tsai, 1999). There is modest evidence that clonidine may reduce symptoms of hyperactivity in children with Autism (Frankhauser, Karumanchi, German, Yates, & Karumanchi, 1992; Jaselskis, Cook, Fletcher, & Leventhal, 1992). The use of clonidine for managing hyperactivity and sleep problems in children with Autism has escalated in recent years, although the empirical data supporting its efficacy are scanty. Desipramine is a selective norepinephrine uptake inhibitor that has been shown to reduce hyperactivity in children with Autism (Gordon et al., 1992).

Psychostimulants

Again, very few studies have been done to assess the effects of psychostimulants, such as Ritalin and d-amphetamine. However, initial results suggest that these drugs may be helpful in improving attention and social responsiveness (Vitriol & Farber, 1981), irritability (Quintana et al., 1995), and hyperactivity (Geller, Guttmacher, & Bleeg, 1981; Handen, Johnson, & Lubetsky, 2000). Other studies have shown deleterious effects following the use of stimulants in patients with pervasive developmental disorders, including overactivity and stereotypical behavior (Schmidt, 1982), fearfulness, separation anxiety, and increased hyperactivity (Realmuto et al., 1989), and agitation, aggression, and motor and phonic tics (Volkmar, Hoder, & Cohen, 1985).

Opiate Agonists

Naltrexone has been shown to reduce hyperactivity in individuals with Autism (Campbell et al., 1993; Campbell, Overall, Small, & Sokol, 1989; Kolmen, Feldman, Handen, & Janosky, 1995, 1997; Willemsen-Swinkels, Buitelaar, Nijhof, & Van Engeland, 1995; Willemsen-Swinkels, Buitelaar, & Van Engeland, 1996). Opiate blockers may also reduce self-injurious behaviors (Werry & Aman, 1999).

Vitamin and Diet Therapies

It should be noted that rigorous empirical studies of the efficacy of vitamin and dietary treatments for Autism are lacking. Nevertheless, there has been some evidence for metabolic abnormalities, including high or low excretion of uric acid (Coleman & Gillberg, 1993; Lis, McLaughlin, Lis, & Stubbs, 1976), high excretion of hippuric acid (Lis

et al., 1976), low urinary tyrosine (Visconti et al., 1994), and excretion of peptides (Kniesberg, Wiig, Lind, Nodland, & Reichelt, 1990; Reichelt, Kniesberg, Nodland, & Lind, 1994), related to gut symptomatology (i.e., “leaky gut”) in some individuals with Autism. A few studies have examined vitamin and dietary therapies to address metabolic abnormalities. For instance, pyridoxine (vitamin B₆) has been reported to improve social behavior and language, increase interest in the environment, and reduce aggression in subjects with Autism (Coleman, 1989; Kleijnen & Knipschild, 1991; Lelord, Barthelemy, & Martineau, 1988). Folic acid has been reported to decrease hyperactivity and increase attention and social behavior in subjects with Autism with Fragile X syndrome (Coleman, 1989). The diet most often associated with the treatment of Autism is the low-casein and/or low-gluten diet (Kniesberg et al., 1990). This diet is purported to improve symptoms of Autism by removing proteins that produce toxic peptides. A diet low in casein and gluten was reported to increase social interaction, improve language, and increase interest in the environment after 1 year (Kniesberg et al., 1990). More research on dietary intervention is clearly needed.

PSYCHOSOCIAL INTERVENTIONS

A number of psychosocial treatments are available for individuals with Autism. These treatments target skill domains that are typically impaired in Autism, including social, cognitive, language, and behavioral functioning. Regardless of the treatment approach, it is important that intervention begin at an early age for the best prognosis.

Early Intervention

Early social and language input is critical for normal brain and behavioral development (Mundy & Neal, 2001; Rogers, 1998). If Autism can be identified early and intervention can begin during the first few sensitive years of life, there is the greatest potential for having a significant impact on the developing nervous system and improved social and behavioral outcomes for children with Autism (G. Dawson, Ashman, et al., 2000; Rogers, 1998).

Several studies suggest that early intervention can result in dramatic improvements in some children with Autism (Birnbauer & Leach, 1993; G. Dawson & Osterling, 1997; Fenske, Zalenski, Krants, & McClannahan, 1985; Harris, Handleman, Gordon, Kristoff, & Fuentes, 1991; Lovaas, 1987; McEachin et al., 1993; Rogers, 1998; Sheinkopf &

Siegel, 1998). As summarized by G. Dawson and Osterling, Green, Brennan, and Fein (2002), Rogers, and the National Research Council (2001), although intervention approaches have varied across different outcome studies, most have several features in common:

1. A focus on the curriculum domains of attention, imitation, language, toy play, and social interaction;
2. Programs that incorporate developmental sequence;
3. Teaching strategies that offer a high level of support for the child, many of which rely on principles of applied behavioral analysis (see later discussion);
4. Specific strategies focused on reducing interfering/problem behaviors;
5. A high level of involvement of parents;
6. Careful transitioning from one-to-one teaching to small groups;
7. Highly trained staff;
8. High levels of supervision of therapists;
9. Intensive intervention consisting of about 25 hours a week of structured intervention lasting for at least 2 years; and
10. Onset of intervention by 2 to 4 years.

When these features are present, results have been impressive for a subgroup of children, including robust gains in IQ, language, and educational placement (G. Dawson & Osterling, 1997; Rogers, 1998). There is evidence that very early intervention, by 2 to 3 years of age, results in more positive outcomes than intervention that begins later (Simeonsson, Olley, & Rosenthal, 1987).

There is some debate as to the optimal number of hours of early intervention. Lovaas’s (1987) original study advocated 40 hours per week of one-on-one behavioral intervention during the preschool period. The National Research Council (2001) currently recommends at least 25 hours of structured intervention for children with Autism, with a strong emphasis on one-on-one intervention, which can include specialized education, speech and language therapy, occupational therapy, applied behavioral analysis, and other services that promote the child’s communication and social development.

To date, most studies on the effectiveness of early intervention have had significant methodological limitations (for reviews, see G. Dawson & Osterling, 1997; Rogers, 1998; T. Smith, 1999). Lovaas’s (1987) original study showing positive effects of early intervention, although important and provocative, had methodological limitations with respect to choice of outcome measures, selection bias, and representativeness of sample (Gresham & MacMillan, 1998). In a randomized study, T. Smith,

Groen, and Wynn (2000) compared a group of 15 children receiving “intensive intervention” consisting of an average of 24 hours of early intervention weekly (with reduction in hours after year 1) to a group of 13 children whose parents were taught to use early intervention techniques for 5 hours per week over a 3- to 9-month period, with consultation every 3 months thereafter. Children began treatment at about age 3 and were seen at follow-up at about age 7 to 8. At follow-up, the intensive treatment group had a statistically significant advantage over the parent training group in IQ, visual-spatial skills, and language development, but not adaptive behavior. Within the intensively treated group, children with a diagnosis of PDD-NOS obtained higher outcome scores than those with a diagnosis of Autism, although these differences were not statistically significant. In both groups, large individual differences in response were apparent. In the intensive treatment group, a standard deviation of 24 IQ points was found at outcome. Some children in the intensive treatment group obtained high achievement on language tests, but others remained nonverbal and severely cognitively impaired.

Given the tremendously high cost and burden of early intervention for parents and society, it is important that the efficacy of early intervention be examined more thoroughly. Moreover, additional research is needed to determine how best to transfer the university-based treatment model to community school settings, which have fewer resources available (Gresham & MacMillan, 1998). In the next sections, early intervention approaches on which data have been published are discussed.

Applied Behavior Analysis

Applied behavior analysis (ABA) refers to a set of principles, including operant learning, that are applied in an individualized, one-on-one setting to promote communication, social, adaptive, and academic functioning. ABA, specifically a traditional approach called discrete trial teaching, was first applied to children with Autism in the 1960s by Ivar Lovaas at UCLA. Since that time, the techniques used in the ABA approach to treating children with Autism have become much more varied, with discrete trial teaching being only one of many effective ABA strategies.

In general, ABA involves the functional analysis of the child’s behavior and motivation. It involves clearly defined and observable goals based on the child’s abilities and challenges and regular (i.e., daily or weekly) collection of data to assess progress. These techniques are often used in home programs to supplement educational services received in the community, and a number of preschool inter-

vention programs have modified these techniques for use in the classroom (S. R. Anderson, Campbell, & Cannon, 1994; Handleman & Harris, 1994; McClannahan & Krantz, 1994; Strain & Cordisco, 1994).

Naturalistic Interventions Incorporating Applied Behavior Analysis Principles

In recent years, more naturalistic ABA strategies have included incidental teaching (Hart & Risley, 1980; McGee, Daly, Izeman, Mann, & Risley, 1991), natural language paradigm or pivotal response training (an approach that focuses on pivotal behaviors, such as motivation and attention; R. L. Koegel & Koegel, 1995; R. L. Koegel, O’Dell, & Koegel, 1987; Laski, Charlop, & Schreibman, 1988; Schreibman & Koegel, 1996), milieu teaching (Kaiser & Hester, 1996), and the Denver model (Rogers, 1998; Rogers & Lewis, 1989). These approaches emphasize naturally occurring teaching opportunities and consequences that encourage child motivation and initiation of learning. Some approaches emphasize affective engagement and social relatedness (Rogers & Lewis, 1989).

Studies have shown that naturalistic approaches can result in more generalized responding, increased spontaneity, and improved efficiency in teaching acquisition and generalization simultaneously (Schreibman, 1997; Schreibman & Koegel, 1996). Further, these approaches have been shown to be associated with more positive affect and fewer disruptive behaviors than more traditional ABA teaching approaches (R. L. Koegel & Egel, 1979; Schreibman, Kaneko, & Koegel, 1991). These approaches are currently being used in the Walden Program at Emory University (McGee, Daly, & Jacobs, 1994), the Learning Experiences, an Alternative Program (Strain, Kohler, & Goldstein, 1996), and the Denver treatment model developed by Sally Rogers (Rogers & Lewis, 1989).

Treatment and Education of Autistic and Related Communication-Handicapped Children

The Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH) program was developed in the 1960s by Eric Schopler and colleagues (Schopler, Mesibov, Shigley, & Bashford, 1984). This approach emphasizes visual structure and environmental modifications and supports to promote independence and maximize generalization of skills. The TEACCH program uses the visual, mechanical, and rote memory strengths of many children with Autism to bootstrap less developed language, imitation, cognitive, and social skills. For example, the classroom is structured to provide children with predictability and to ease transitions from one

activity to the next. Visual formats, such as picture schedules to outline tasks and show what is expected and what comes next, are emphasized, as they are easily understood and lessen anxiety, frustration, and tantrums. Such work systems are especially useful for promoting attention, independent functioning, and successful completion of tasks. Other intervention programs borrow from this approach, for example, by employing visual cues and environmental supports to increase comprehension, facilitate the exchange of information, and decrease problem behaviors (Dalrymple, 1995). In practice, many TEACCH strategies are incorporated into both traditional and naturalistic ABA programs.

Language and Communication Interventions

Improved language interventions that include motivational techniques, such as following the child's lead, emphasizing the child's motivation to respond, and providing frequent opportunities for expressive language in natural settings, have been shown to have a significant impact on the verbal communication skills of children with Autism. As many as 85% to 90% of children who began such interventions before the age of 5 learned to use verbal communication as a primary mode of communication (L. K. Koegel & Koegel, 1995; McGee et al., 1994). For children who were initially nonverbal, these interventions yielded greater increases in immediate and deferred verbal imitation, word production, and spontaneous utterances as compared to more structured approaches (e.g., discrete trial training; R. L. Koegel et al., 1987). For verbal children with delayed language, greater improvements in verbal attempts, word approximations, word production, and word combinations were found compared to discrete trial training formats (R. L. Koegel, Koegel, & Surratt, 1992). Effective procedures are currently available for teaching children with Autism to use language functions such as asking questions and other verbal initiations, which are necessary for social competence (Hung, 1977; L. K. Koegel, Camarata, Valdez-Menchaca, & Koegel, 1998; L. K. Koegel, Koegel, Shoshan, & McNerney, 1999; B. A. Taylor & Harris, 1995; Warren, Baxter, Anderson, Marshall, & Baer, 1981).

Augmentative and alternative communicative (AAC) systems are also available for nonverbal children with Autism, although problems with failure to generalize and use these systems spontaneously have been noted by some (Mirenda & Mathy-Laikko, 1989; Schlosser, Belfiore, Nigam, Blischak, & Hetzroni, 1997; Stiebel, 1999; Storey & Provost, 1996). Such systems include sign language, photographs, picture exchange systems, communication books, and computer systems, among others.

Interventions Targeting Social Behavior

A number of interventions have been shown to facilitate social interactions among children with Autism of all ages. Play-based interventions were shown to enhance the social interactions of preschool-age children with Autism with parents and other adults (G. Dawson & Galpert, 1990; Krantz & McClannahan, 1998; Rogers, Herbison, Lewis, Pantone, & Reis, 1986; Stahmer, 1995). To increase peer interactions, typically developing peer models are taught to initiate play with perseverance (Lord, 1984; Strain et al., 1996). This approach has been shown to increase the social interactions of young children with Autism, and both generalization and maintenance of effects were demonstrated (Goldstein, Kaczmarek, Pennington, & Shafer, 1992; Hoyson, Jamieson, & Strain, 1984; Odom et al., 1999; Odom & Strain, 1986; Strain, Kerr, & Ragland, 1979; Strain, Shores, & Timm, 1977). However, increases have not always generalized to untrained peers (Lord, 1984).

For school-age children and adolescents with Autism, a number of techniques have been shown to increase social interactions, including pivotal response training to teach sociodramatic role play (Thorp, Stahmer, & Schreibman, 1995), video modeling (Charlop & Milstein, 1989), direct instruction (Coe, Matson, Fee, Manikam, & Linarello, 1990), social stories (Gray & Garand, 1993), peer-mediated approaches (Lord, 1984; Lord & Magill-Evans, 1995; Shafer, Egel, & Neef, 1984; Strain et al., 1979), social skills groups (Kamps, Leonard, Vernon, Dugan, & Delquadri, 1992; Ozonoff & Miller, 1995), and visual cuing (Krantz & McClannahan, 1993, 1998).

Special Education Services

There are a number of classroom options for children with Autism, ranging from fully self-contained special education classrooms to inclusion in regular education classrooms with modifications. Federal legislation requires that schools provide fair and unbiased evaluations to determine eligibility for special services. These special services, including accommodations and objectives, form the basis of an individualized education program. However, a diagnosis of an Autism Spectrum Disorder does not always guarantee eligibility for special education services. In these cases, parents can rely on Section 504 of the Federal Rehabilitation Act of 1973, which provides for appropriate public education for all people with disabilities, with "disabilities" broadly defined. Under Section 504, educational accommodations and modifications can be stipulated to help children with Autism succeed in school. Such accommodations include posted classroom schedules, written instructions, a special

work area or divider to remove distractions, allocation of additional time to complete assignments, permission to take exams in an alternative format or to have extra time, behavior modification plans (which may involve token or other systems to reinforce appropriate behavior), handwriting alternatives (e.g., tape-recorded lectures and notes), and special help with transitions (Ozonoff et al., 2002).

Occupational Therapy, Sensory Integration Therapy, and Auditory Integration Therapy

Very few controlled studies have been conducted to examine the efficacy of occupational therapy, sensory integration therapy, and auditory integration therapy in addressing sensory and fine and gross motor impairments in Autism. Occupational therapy is a common component of intervention programs for young children with Autism and is designed to promote skill development in the context of play and adaptive behavior. Sensory integration therapy (Ayres, 1972, 1979) emphasizes the relation between sensory experiences and behavior. Strategies include the use of vestibular, proprioceptive, and somatosensory activities, such as swinging and deep pressure, to promote functional and adaptive responses to sensory stimuli. Although sensory and motor impairments are common among children with Autism, these interventions have not been well validated empirically (G. Dawson & Watling, 2000).

Adults with Autism

State government agencies that provide services to people with disabilities may provide some funding to families for vocational training and assisted or semi-independent residential living programs.

Vocational Skills Training and Employment Options

Research has shown that training in vocational and adaptive living skills is best achieved in a naturalistic setting (Schopler & Mesibov, 1983). Further, persons with Autism perform best in occupational settings that provide continued support and in vocations that involve their particular interests as well as concrete and linear processes (Mathews, 1996; Sugiyama & Takahasi, 1996). The main agency that provides vocational assistance to individuals with disabilities is the Rehabilitation Services Administration, which has chapters in each state. Employment options include sheltered employment at a job site operated by the local vocational training agency, with jobs such as mail processing, woodworking, and product assembly; secure employment, similar to sheltered employment with the exception that the

adult with Autism is provided training in improving job skills and behavior, which allows for the possibility of eventually working in a more competitive and independent workplace; supported employment, working alongside adults without disabilities but with the support and supervision of a job coach (i.e., a professional or volunteer employed by the employment training agency, not the employer); and competitive employment, completely independent work requiring a mastery of both job skills and behavior (Holmes, 2000).

Residential Living Programs

In the past, the only choices of living options for adults with Autism were to keep these individuals at home with their parents or place them in a segregated institution. In more recent years, there has been a movement toward community integration, although not every area of the country offers all of the following options: independent living in a house or apartment with support services provided by agencies and families to assist with complex issues such as money management; supervised group living, usually in a residential setting with trained staff; adult foster care, wherein families receive government money to open their home to adults with disabilities; skill development homes, similar to adult foster care homes with the exception that these families are trained to work with individuals with Autism; and state-operated or privately run institutions (Autism Society of America, 2001).

Independent Living

With effective intervention and social support, many adults with Autism are able to lead independent, or semi-independent, lives that are productive and satisfying. The special strengths often associated with Autism, such as strong rote memory and excellent visualization skills, as well as artistic and musical capabilities, have allowed many persons with Autism to work productively. Social skills training and adult support groups have helped such individuals develop meaningful relationships, including friendships and marriage.

CONCLUSION

This is an exciting period in research and clinical practice aimed at helping individuals with Autism spectrum disorders, as increasingly more research is being conducted that will improve our understanding of the cause, nature, course, and treatment of these disorders. As children are recognized at earlier ages and high-quality early behavioral interventions are more readily provided, the long-term prognosis for individuals with Autism is improving, with a substantial

subgroup attaining college-level education, satisfying relationships, and independent lives.

Progress in understanding the cause, nature, and treatment of Autism will depend on an integration of scientific approaches from genetics, cognitive neuroscience, and psychology (developmental and clinical). This is a fundamental premise of the discipline of developmental psychopathology (Cicchetti, 1984, 1990, 1993). The rapidly emerging fields of the neuroscience of emotion and social behavior will inform our understanding of Autism, just as studies of Autism are informing those same fields. New findings and approaches to studying gene-environment relations and genetic regulation of brain development and plasticity surely will inform our understanding of Autism and help elucidate the effects of early intervention on brain development and behavior in Autism. Studies of the impact of early interventions on brain and behavioral functioning in young children with Autism will allow us to learn about the development and plasticity of neural systems mediating face processing, imitation, and language, among others. The genetics of Autism will allow us to understand the genetic bases of social and language abilities and help explain normal variability in the phenotypic expression of these abilities.

Discovery of Autism susceptibility genes will likely have a significant impact on how we understand the behavioral phenotype of Autism, its subtypes, early detection, and how to improve clinical intervention. For example, as genes are discovered and animal models are developed, we will begin to understand how early signs of Autism are manifest and develop and how altered experience related to brain dysfunction affects the development of later brain structures and function. We very likely will be able to identify infants at risk for Autism based on the presence of Autism susceptibility genes. This will lead to methods of very early intervention. As many symptoms associated with the Autism syndrome might be caused by the downstream consequences of an early altered trajectory of brain and behavioral development, very early intervention might potentially have a tremendous impact on outcome for many children. As such, we can hope that eventually, some cases of Autism might be preventable.
